There are cases occurring in feeble and aged individuals in which we must almost entirely neglect treatment of the fracture to save the patient's life, and many cases that are going to die under any treatment, or under no treatment. There is no doubt that this class of cases is real, but *over-regard* for the *patients' safety* is apt to lead to *under-regard* of the *problem* of *treatment.*

Most cases of hip-fracture can be treated with regard to the lesion—treated surgically—and are apt to be more rather than less comfortable, if furnished proper support. There can be no rule in this matter, and no statement may be made safely save that the number of cases in which surgical treatment may not be carried out is small.

Leaving this small class of cases aside, the factor *first* to be considered is the lesion.

First, as to the fractures of the base of the neck,—the extra-capsular type. In these, our problem concerns two things—avoidance or correction of deformity, and fixation of the fragments till repair is solid. We need have no fear in these cases of breaking up the impaction. The deformity to be guarded against is practically always: first, eversion; secondly, a diminution of the angle of the neck with the shaft,—a coxa vara deformity. (Figs. 21, 24, and 25.) Simple rotation takes care of the first, the second is to be corrected by traction alone, or traction with abduction. The success of this correction is to be appraised by measurement of the length of the leg taken from the anterior superior spine to the inner malleolus, or to the heel. These correction manoeuvres can hardly be done without anaesthesia—at least I have tried it but once, but the anaesthesia may be very light. If anaesthesia is not practicable, we must accept imperfect correction.

Now as to fixation: We have to guard not only against immediate recurrence of displacement, but against the tendency to slow yielding to muscle pull, even after union has begun. (Figs. 23, 24, 25.)

The usual routine, sand bags, or long splints, or moderate weight traction, do not accomplish this.

We may work effectively in this direction in three ways. We may adopt the method known as Whitman's, (though Shaffer originated it back in 1886), the abduction method. Shaffer

* Reported in *American Journal of Orthopedic Surgery*, May, 1911.

combined direct pressure on the trochanter with abduction. The method as now employed is pure abduction. It rests on the theory that if the femur is abducted far enough the limit of motion at the hip is reached, the upper fragment stops, and the shaft is further abducted till it comes into normal relation to the upper fragment. This is approximately true at least, and more than that, forced abduction brings the long, strong adductors taut, and so drives the fragments into contact. (Fig. 26.) This brings in another factor, the possibility of fragments slipping by under this pressure. (Fig. 27.)

I have felt safer, before abducting, in correcting the deformity by rotation and traction, then *impacting* lightly with a *mallet*, then carrying the leg into abduction. In this way the chance of slipping seems to be obviated. I have done it in a number of cases and it seems to work out well. (Figs. 28, 29.) These fractures are apt to be splintered more or less, therefore the force used in impacting must be guarded, but in no case has any harm been done. I do not claim that even in this way *perfect* reduction can be obtained, or that we have positive assurance against the slow development of coxa vara.

It is fair, however, to claim very satisfactory results from abduction alone. (Figs. 26, 27, 30.)

In favor of the abduction position is another fact little dwelt on, namely: the avoidance of contracture. In all hip-fractures, the tendency is for the leg to pull over into adduction, and when the patient begins to get about, the adduction contracture is a very serious and often permanent factor in the lameness. (Fig. 31.) This the abduction treatment avoids, a rather important item.

Now there is an altogether different way of going about the handling of these cases, namely,—the so-called "anatomic" method of Ruth of Des Moines, used earlier by Phillips and by Maxwell, a method we in the East know little about. I have lately had a chance to see Ruth apply it, and to discuss the matter with him. He applies it to everything, which seems irrational to me. As yet, all his specimens and tested results shown are of fractures at the *base* of the neck. There is something in the method; the results seem good, and it may be as good as the impaction-abduction scheme I am using *for these inter-trochanteric cases.*

The treatment consists of manual reduction in flexion, (to relax the ileo-psoas) then downward traction to do away with the shortening, then the application of substantial weight-traction in the line of the limb, and lateral traction on the thigh next the groin. There is no reason why this traction treatment may not be carried out in moderate abduction. It looks more comfortable than a plaster spica, and it may be that Whitman and I must abdicate in Ruth's favor for *this class* of *basal* fractures.

Now as to the fractures of the neck proper, the intra-capsular type. In this class of cases I am going to leave Ruth's method out of consideration; for this class it is *not* anatomic so far as I can reason, and it seems inevitable that lateral traction must tend to separate the fracture surfaces; a disadvantage in these cases far out-weighing the question of improved position, for our chance of union depends upon *fixed* and *absolute contact.* Moreover, I have not yet seen any real analysis of results in *this class* of cases under this routine.

Neither do I agree with Whitman entirely, so here is my notion of the matter.

There are cases in which there is only a crack, or a negligible displacement only; others, more often seen, in which there is deformity, but not enough to justify the anaesthesia almost essential to any accurate correction.

These cases I am perfectly content to let alone, holding the legs fixed (usually with sand bags) in an abduction sufficient to ensure against adduction contracture. Only in a minority of the cases has it seemed to me justifiable to use the plaster spica for fixation, except in cases calling for actual correction of position.*

There remain the many cases of true neck-fracture (so-called intra-capsular fractures) in which there was no real impaction at the start, or in which the impaction has given way spontaneously, or in which the x-ray shows the impaction to be poor and the surfaces badly fitted, or in which there is really considerable eversion, or shortening.

In all these cases I agree with Whitman—*the position should be corrected.* This does not usually mean "breaking-up" the impaction loosely. The impaction is remodelled, so to speak, becoming looser, but not really loose at any stage in the proceeding.

I also agree with Whitman that fixation in abduction is desirable but here is where I go further. After correction, before the abduction, I impact!

With the bone-surfaces accurately adjusted by proper traction and rotation, impaction is carried out with a large heavy mallet, slowly swung, striking the trochanter, which is protected with felt. The impaction *does* take place, corresponding to the accidental, primary impaction of the lucky cases, probably never very deep, but enough to ensure better contact. All we know about these fractures tells us that repair (slow at best, especially on the part of the poorly nourished upper fragment) depends on *accurate coaptation*, and *absolute fixation* of the broken surfaces. ***This can be obtained with the mallet.*** Whether it can be obtained by mere abduction we do not know. (Figs. 32, 33, 34.)

* Since the above was written, I am using the spica more frequently, because I find these old folks easier to handle and more comfortable, if treated in this way.

None of us can talk much about series of cases, accurately studied; these patients are curiously hard to follow, it is nearly impossible to get them back to an x-ray machine, and only by studying "push and pull" x-rays, can we ever be sure about the existence of bony union in any case. (Figs. 14, 15, 17, 18, 19, 20, 21, 22.)

About three years ago I first began taking these "push and pull" plates. If we have one plate taken while a traction of perhaps fifty pounds is exerted by hand on the foot, and another in which an upward thrust is exerted, there is even in the best fibrous unions, a perfectly definite difference in the pictures. Even where the up and down motion is so little as to be in doubt, the comparisons of the two positions show at least a rocking head. (Figs. 15, 17.) These pictures are easy to take; they are conclusive, and only after testing our fracture results in this way can we justifiably talk about *bony* union.

In the meantime, I regard impaction as at least an important safe-guard. In the extracapsular cases it helps hold them (Figs. 28, 29), but is not essential. In the fractures of the neck proper I believe we have no right to leave the fracture without making sure there is impaction. The failure of bony union is too serious to take chances on. (Figs. 32, 33, 34.)

Open operation calls for only a short notice. Never in order in fresh cases, it is restricted to those cases of fracture of the neck in which the closed method has failed.

Radical refreshing of the surface of fragments through the anterior route of approach, and correction of position is the only method. When we have gone so far, it is probably best to nail the fragments. I have had successes with simple fixation in forced abduction and have tried impaction with good result, but the nail is probably always advisable. It must be a *temporary* nail, by choice a 4½ inch or 5 inch wire-nail spike driven in through a small incision through trochanter and neck till it appears in the gap between fragments, then driven forward three-quarters of an inch farther. Its head projects through the skin enough to get hold of it, comes out easily after three to six weeks, and leaves no irritant foreign body behind after it has done its work of fixation. (Fig. 35.)

In some cases (a minority, I fear) I have been able to demonstrate bony union.

In conclusion, I believe in the abduction principle, but not as a cure-all method; and I believe no less firmly in the principle of ensuring real fixation by artificial impaction, again, not as a cure-all, but as a method of real value.

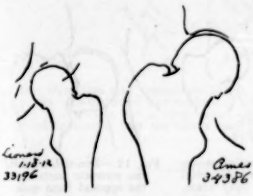

FIG. 1.—Crack of femoral neck: displacement inconsiderable.

FIG. 2.—True impaction of femoral neck.

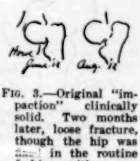

FIG. 3.—Original "impaction" clinically solid. Two months later, loose fracture, though the hip was [illegible] in the routine fashion, with a special nurse in charge.

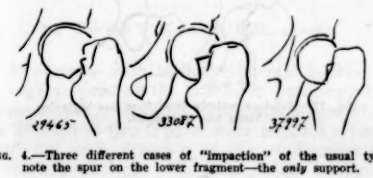

FIG. 4.—Three different cases of "impaction" of the usual type: note the spur on the lower fragment—the *only* support.

FIG. 5.—Loose fracture: Two positions taken on the same day (not "push and pull" pictures).

FIG. 6.—Supposedly impacted fracture that "fell apart." The x-ray confirms the illusory sort of impaction present.

FIG. 7.—Types of basal fracture.

FIG. 8.—Other types of base fracture of not unusual occurrence.

FIG. 9.—"Intertrochanteric" hip fractures.

FIG. 10.—Crack of femoral neck. Picture 18 days later, showing absorption, though union was in the end by solid bone.

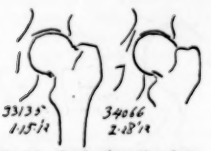

FIG. 11.—Crack: absorption shown 44 days later. Admirable clinical result, probably bony union.

FIG. 12.—Non-union; note the sclerotic surfaces of the opposed bone ends.

FIG. 13.—Fracture entirely loose from the beginning. Views four days apart.

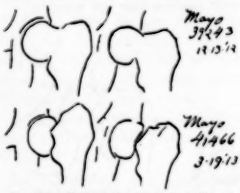

FIG. 14.—Progressive loosening; fibrous union; above, "push and pull"; below, the same case three months later.

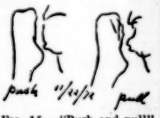

FIG. 15.—"Push and pull" x-ray five months after the accident. Here as in Fig. 17, rotation of the head is an important part of the displacement.

FIG. 16.—"Impaction" that broke up in bed under very careful treatment.

FIG. 17.—Same case as Fig. 16, "push and pull" five months later; close fibrous union; note that the displacement is hardly more than a *rotation* of the *head* of the femur.

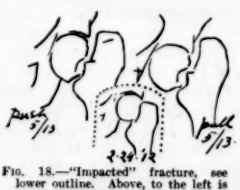

FIG. 18.—"Impacted" fracture, see lower outline. Above, to the left is the "push" picture, to the right the "pull" outline. Obviously, there is only *fibrous* union. The clinical result is poor.

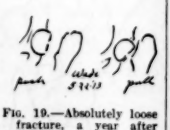

FIG. 19.—Absolutely loose fracture, a year after the injury. "Push and pull" picture. The clinical result was very poor.

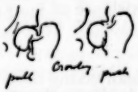

FIG. 20. — *Close* fibrous union, push and pull pictures.

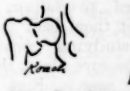

FIG. 21. — Base fracture (old) with coxa vara. The "push and pull" pictures in this case were identical: *i.e.* union was by bone, as *always* in treated basal fractures.

FIG. 22.—Base fracture (old) showing "push and pull" composite. Outlines identical: *i.e.* union by *bone* as *always* in this type.

FIG. 23.—Subtrochanteric fracture. There was grotesque deformity but solid union. Later I took this fracture apart, spiked it and got a solid union with a very serviceable hip as a result.

FIG. 24. — Base fracture, — typical. Shows the development of moderate coxa vara deformity during a month of treatment in *fixation without abduction*.

FIG. 25.—Basal fracture: outline to the right shows the development of coxa vara deformity (slight) in four weeks of *fixation without abduction*.

FIG. 26.—Basal fracture, abduction treatment (in plaster spica); results two weeks later, neck shortened, but angle of neck near normal.

FIG. 27.—Basal fracture: abduction in plaster spica.: Riding by of fragments under the abduction pull.

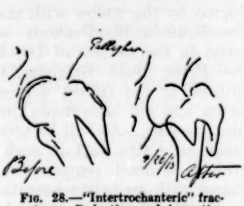

FIG. 28.—"Intertrochanteric" fracture. Reduction and impaction with the mallet. Distinctly improved position. Union solid. Clinical results excellent.

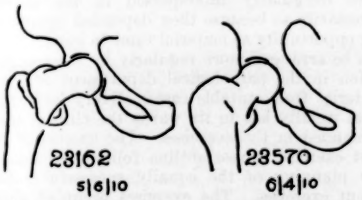

FIG. 29.—Base fracture before and after *impaction with the mallet*.

FIG. 30.—Neck fracture proper. Before and after forced abduction and application of a plaster spica. Note the betterment in angle and in shortening.

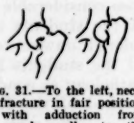

FIG. 31.—To the left, neck fracture in fair position with adduction from muscle pull; to the right abduction from actual bony deformity: I believe the two to be equally crippling.

FIG. 32.—Tracing to the left shows the original "impaction." The patient was discharged, but presently returned with the obviously loose fracture shown in the middle plate. Under ether, impaction was performed with the mallet. Clinically the result was excellent; for detailed data see the outline at the right.

FIG. 33.—Loose fracture of neck, shown after impaction with the mallet. The patient died of lung edema after a month, but with the impaction still solid.

FIG. 34.—Much shortened neck fracture. Reduction under ether; impaction with mallet; plaster spica in abduction; result shown at two months. Union apparently solid. Later clinical result excellent.

FIG. 35.—Operative case (temporary spike), six months after operation (14 months after the accident). There is a close union but it is a fibrous, not a bony union. Results of operation are good but operation does not ensure bony union.

THE EXPERIMENTAL METHOD AS UTILIZED IN THE CLINICO-PATHOLOGICAL CONFERENCE.

BY HOWARD T. KARSNER, M.D., BOSTON.

Experience with the experimental method as a regular part of the course in pathology has demonstrated its value. How much time shall be allotted to this type of work remains a problem for each director of the undergraduate work in pathology. The same is true in regard to the degree of participation by the student in such exercises. A scheme for the participation of students in the actual performance of experiments has been outlined in a previous paper[1] and has been operated successfully for three years in the Harvard Medical School. Criticism has been offered to the effect that much of the technique necessary to carrying on the work must be learned by some of the students and that they readily forget these details. This is probably true, but time limitations are such that a course of this kind cannot have as its function instruction in technical procedures to large classes. The participation of the students must have for its purpose contact with experimental procedures, not so much for the technique as for the point of view which it engenders. This point of view has its value not only in pathology but in all the work of the medical course and it is a point of view that cannot be gained by observation of the results of others nearly so well or so permanently as by actual participation, a truism that forms the basis for all laboratory training. In its ultimate analysis, experimental pathology means simply the adoption by the trained pathologist of the methods of physiology, chemistry, surgery, immunology and bacteriology. The teaching of experimental pathology then is simply the utilization of these methods in explaining the processes and products of disease. Properly applied this form of teaching does not ignore the anatomy and histology of the lesions; to the contrary, it emphasizes the importance of the lesions by showing the correlated functional change. It is difficult for the bio-chemist and physiologist to make extensive clinical application of their

[1] Karsner, H. T.: The Function of the Experimental Method in the Course in Pathology, BOSTON MED. AND SURG. JOUR., 1912, vol. clxvii, p. 531.

work in the undergraduate courses because the students at that stage in the graded course have little or no knowledge of pathological anatomy. Hence, the teaching of pathological physiology in its broadest sense devolves upon the experimental pathologist. The gap between the clinic and the fundamental sciences is one of the penalties of the graded course and even with the institution of work in experimental pathology it is not completely bridged. Unfortunately, from this particular point of view, much of the work in the fundamental sciences is taught with reference to pure science rather than to the applied science of medicine and in many respects this is necessary. To overcome this difficulty various schemes have been devised, such as the new method of examinations in the Harvard Medical School whereby it is necessary for the student to pass a general collective examination in all the subjects of the first two years at the end of that period and in all the subjects of the second two years at the end of his course. There can be no question of the value of this particular scheme. Uniformity of ideals on the part of teachers and close coordination of the teaching of the fundamental sciences and of the clinical branches can do much to aid the student in correlating in his own mind all the subjects of the medical curriculum. The necessity for such close coordination of teachers has been made the basis for the appointment to the Children's Hospital in affiliation with the Harvard Medical School of the heads of the departments of bacteriology, bio-chemistry, pharmacology, physiology and experimental pathology, the heads of these scientific departments to have rank on the visiting staff with the visiting physicians and surgeons. This cannot but react beneficially on the work of the school and the hospital and to the mutual advantage of physician, student and patient, in regard to diagnosis and treatment as well as teaching and investigation. It must have been the same spirit of cooperation that led to the establishment abroad and in this country of the various exercises in clinico-pathological correlation. With the modern development of the fundamental sciences and the institution of undergraduate work in experimental pathology such exercises have become inadequate and it becomes necessary to include in such conferences the related alterations of function. It would be well if the conferences could command the services of workers in the various special fields and it is hoped that the future will produce such a cooperative scheme, but at the present time the experimental pathologist is obliged to fill in the details of processes and functions which are necessary to make clear the relation between the pathological lesions (including their relations to each other) and the clinical case. That such a scheme is practicable is illustrated by the account of the exercises which have been conducted by the writer with the invaluable aid of Dr. Francis W. Peabody whose clinical material in the service of Dr. H. A. Christian at the Peter Bent Brigham Hospital has been utilized to the fullest degree, and whose sympathy and aid have made the fulfillment of the idea possible. As will be seen, Dr. Peabody has taken an active part in each exercise. The exercises outlined require the affiliation of the school with an active hospital, in which clinical cases are studied intimately, careful records kept and autopsies performed upon a large number of fatal cases. The exercises, as conducted, were irregularly interspersed in the course, necessarily so because they depended upon seizing opportunity as material came to hand. They can be arranged more regularly by the accumulation in the pathological department of gross material from suitable cases. Every large hospital usually has in its wards the clinical cases demanded in the exercises. The success of the first exercise, whose outline follows, stimulated the planning of the equally successful subsequent exercises. The exercises occupied about three hours, a rest period of ten minutes being provided at the end of each hour. They presuppose considerable preliminary work on the part of the students and it has therefor been considered unwise to attempt these exercises until the students have had eight weeks work in pathology as conducted under the concentration method of the Harvard Medical School.

EXERCISE 1. Aortic valvular disease.

A. Seven formalin preserved human hearts showing aortic disease were given to seven pairs of students; the hearts were studied and the students were quizzed by Dr. Karsner in the presence of their classmates, the entire class taking part in the conference on each specimen.

B. Demonstration of physiological tracing of pulse and blood-pressure from a dog with experimental aortic stenosis. The demonstration was by the five students who had participated in the experiment, and the students were reminded that they had listened with the multiple stethoscope to the murmur in this animal.

C. Demonstration by students of physiological tracing of pulse and blood-pressure from a dog with experimental aortic regurgitation.

D. Demonstration by Dr. Peabody of a human patient with double aortic murmur. Students listened to murmurs with multiple stethoscope.

E. Reading of case history of a case of aortic stenosis and summary by Dr. Peabody. Demonstration by Dr. Karsner of the fresh autopsy material from this case. Conference on the pathological anatomy, physiology and clinic of this case by Drs. Karsner, Peabody and class.

EXERCISE 2. Arterio-sclerosis.

A. Demonstration by students of ten gross specimens of arterio-sclerosis; conference.

B. Demonstration by students of adrenalin arterio-sclerosis in the rabbit. Conference on the theories of the development of arterio-sclerosis, including brief discussion of cholesterol sclerosis and lactic acid sclerosis.

C. Demonstration by Dr. Peabody of a case of syphilitic arterio-sclerosis (aortitis).

D. Case history and summary by Dr. Peabody of a case of syphilitic arterio-sclerosis with aortic regurgitation; demonstration by Dr. Karsner of fresh material from this case.

E. Demonstration by Dr. Peabody of radiographs from a case of peripheral arterio-sclerosis.

F. Case history and summary by Dr. Peabody of a case of peripheral arterio-sclerosis; demonstration by Dr. Karsner of fresh autopsy material from this case.

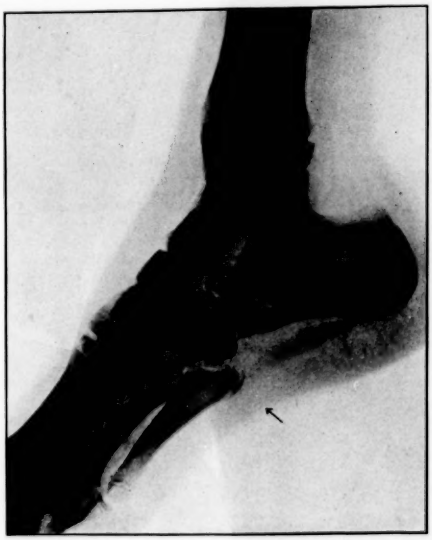
THE VESALIANUM MISTAKEN FOR A FRACTURE OF THE FIFTH METATARSAL BY INVERSION OF THE FOOT.

BY WILLIAM PEARCE COUES, M.D., BOSTON.

THE SAMUEL D. GROSS PRIZE.—It is announced that essays will be received in competition for the Samuel D. Gross Prize of $1500 until January 1, 1915. Further information may be obtained by addressing Trustees of the Samuel D. Gross Prize, 19 South 22nd Street, Philadelphia, Pa.



ankle for this time

Examination, Nov. 23, showed a fairly well developed and nourished little girl, the left ankle, the seat of the traumatism, was not swollen. There was slight ecchymosis over the external lateral ligament region and pain on pressure over the region of the scaphoid. The motions of the ankle were free; the child walked with a limp. A provisional diagnosis of simple sprain, or a possible fracture of the scaphoid, was made. The foot was immobilized in plaster-of-Paris. The x-ray showed what seemed to

work in the undergraduate courses because the students at that stage in the graded course have little or no knowledge of pathological anatomy. Hence, the teaching of pathological physiology in its broadest sense devolves upon the experimental pathologist. The gap between the clinic and the fundamental sciences is one of the penalties of the graded course and even with the institution of work in experimental pathology it is not completely bridged. Unfortunately, from this particular point of view, much

Karsner, Peabody and class.

Exercise 2. Arterio-sclerosis.

A. Demonstration by students of ten gross specimens of arterio-sclerosis; conference.

B. Demonstration by students of adrenalin arterio-sclerosis in the rabbit. Conference on the theories of the development of arterio-sclerosis, including brief discussion of cholesterol sclerosis and lactic acid sclerosis.

C. Demonstration by Dr. Peabody of a case of syphilitic arterio-sclerosis (aortitis).

D. Case history and summary by Dr. Peabody of a case of syphilitic arterio-sclerosis with aortic regurgitation; demonstration by Dr. Karsner of fresh material from this case.

E. Demonstration by Dr. Peabody of radiographs from a case of peripheral arterio-sclerosis.

F. Case history and summary by Dr. Peabody of a case of peripheral arterio-sclerosis; demonstration by Dr. Karsner of fresh autopsy material from this case.

G. General conference.

Exercise 3. Diabetes mellitus.

A. Fifteen-minute review by one of the students of normal carbohydrate metabolism.

B. Discussion by five students on the basis of their own experiments of the influence on carbohydrate metabolism of pancreatectomy, subcutaneous injections of adrenalin, of morphin, of phlorrhizin and of puncture of the floor of the fourth ventricle.

C. Conference directed by Dr. Karsner on the pathological histology of diabetes mellitus on the basis of material studied during the regular course.

D. Resumé of the pathological physiology of diabetes mellitus in its relation to clinical medicine by Dr. Peabody and exhibition of case of diabetes mellitus of protein origin with complete correlated dietary and urinary charts.

Exercise 4. Nephritis.

A. Demonstration by students of seven specimens of chronic nephritis.

B. Reports by students of the acute nephritis of the rabbit produced by uranium nitrate, potassium chromate, cantharadin, diphtheria toxin, sodium tartrate.

C. Demonstration by students of the simultaneous record of kidney volume, blood-pressure and urine flow of a normal dog and discussion of the pathological variations in acute nephritis.

D. Discussion by Dr. Peabody of the phenolsulphonephthalein functional test.

E. Report by students on basis of their own experiment of retention of non-protein nitrogen in the blood in acute nephritis produced by sodium tartrate.

F. Demonstration by Dr. Peabody of case of chronic nephritis.

G. Case history and summary by Dr. Peabody of a case of chronic nephritis with heart hypertrophy; demonstration by Dr. Karsner of the fresh autopsy material from this case.

Similar, but necessarily somewhat briefer, exercises were conducted on the subjects of pneumonia and of serosis of the liver.

The Samuel D. Gross Prize.—It is announced that essays will be received in competition for the Samuel D. Gross Prize of $1500 until January 1, 1915. Further information may be obtained by addressing Trustees of the Samuel D. Gross Prize, 19 South 22nd Street, Philadelphia, Pa.

Clinical Department.

THE VESALIANUM MISTAKEN FOR A FRACTURE OF THE FIFTH METATARSAL BY INVERSION OF THE FOOT.

By William Pearce Coues, M.D., Boston.

The occurrence of the Vesalianum in the foot is so unusual that no reference is made to it in such modern anatomies as Sobotta, Piersol, Gerrish, Morris, Macalister and Gray.

A very few of the x-ray experts with the greatest experience are familiar with its occurrence, and a very few surgeons, although the modern fracture books are silent on the subject of its occurrence and relation to fracture of the base of the fifth metatarsal.

An excellent description is given of this bone, however, in the late Professor Dwight's[1] "Clinical Atlas of the Variations of the Bones of the Hands and Feet." Its rarity may be judged from Professor Dwight's description: "The Vesalianum, corresponding to the bone of the same name of the hand, is the proximal and external part of the tuberosity of the fifth metatarsal. It is excessively rare. I have never seen it in the macerated foot of an adult. Spronck has seen it at birth, and I think I have probably made the same observation. I have once seen it in the skiagraph of a girl of twelve. The entire base of the fifth metatarsal varies much in size. The Vesalianum is usually more or less marked off by a groove on the plantar surface. Grueber has seen a proximal epiphysis not to be confounded with the Vesalianum distinct in the adult."

Professor Dwight shows a plate of the foot of a girl aged 13, showing a separate element very clearly. There was no suspicion of injury. This picture is an exact counterpart of the radiograph of the case reported in every detail.

Report of Case. G. L., 12 years of age, was seen in the surgical clinic of the Boston Dispensary, Nov. 24, 1913. The child was a healthy girl with no history of previous injury to the ankle. While running one week before, she slipped and fell, her left ankle turning under her. She was lame for one week before coming to the clinic. There had been considerable pain in the region of the left ankle for this time

Examination, Nov. 23, showed a fairly well developed and nourished little girl, the left ankle, the seat of the traumatism, was not swollen. There was slight ecchymosis over the external lateral ligament region and pain on pressure over the region of the scaphoid. The motions of the ankle were free; the child walked with a limp. A provisional diagnosis of simple sprain, or a possible fracture of the scaphoid, was made. The foot was immobilized in plaster-of-Paris. The x-ray showed what seemed to

be a fracture of the base of the fifth metatarsal bone, exactly the lesion first described by Robert Jones,[2] in 1902, and of which I have had two recent cases in adults. The occurrence in childhood seemed most unusual. After two weeks or more immobilization, the plaster was removed and an x-ray taken, which showed the supposed fragment in exactly the same condition as before, not united. There was distinct pain on pressure over the base of the fifth metatarsal, however, not present on the right, and it was supposed that the fragment was slow to unite. At the end of another two weeks, the plaster was removed, and another picture taken, which showed the same condition. A picture was now taken of the other ankle, as Dr. H. M. Chase had suggested the possibility of an epiphysis at this place. The radiograph showed the same shell-like bone united to the base of the metatarsal by cartilage. All tenderness had gone from the left foot; the bandage was removed, and weight-bearing begun, with perfect result as regards function. From the tenderness over this region at the time of injury and afterwards, an infraction of the cartilage, uniting the vesalianum to the shaft, could not be ruled out.

The importance of the recognition of this rare abnormality is obvious. Its relation to the cases of fracture of the base of the fifth metatarsal bone by inversion needs further study and elucidation. It is possible that some of the reported cases of this lesion have been this rare anatomical variant, and that others may have been fractures through the line of union to the metatarsal. A radiograph of both feet with a good view of each fifth metatarsal bone should be taken in all cases where the diagnosis of fracture of the base of the fifth metatarsal bone has been made.

New Instruments.

A NEW COMBINATION TONSIL KNIFE.

BY ROCKWELL A. COFFIN, M.D., BOSTON.

IN devising this instrument the author has combined several knives in one, thus simplifying the enucleation of the tonsil.

The broad flat blade may be used for the first incision along the anterior pillar. The curve of the blade conforms to the contour of the tonsil thus facillitating manipulation of the instrument in the supra-tonsillar fossa, the broad flat end acting as a dissecter if necessary.

While the instrument is made sharp for those who prefer it, the author dulls it slightly in order to prevent injuring the pillars after the field of operation is partly covered with blood and also to reduce the liability to hemorrhage. The instrument was made by M. Uhl, Boston.

Medical Progress.

REPORT ON OBSTETRICS.

BY ROBERT L. DENORMANDIE, M.D., BOSTON,
AND
JOHN B. SWIFT, JR., M.D., BOSTON.

PITUITARY EXTRACT IN UTERINE INERTIA.

Edgar[1] reports the use of pituitary extract in seventy cases. In these cases he used the preparations of Burroughs Wellcome & Company, Parke Davis & Company and Armour & Company. For decided action of the drug Edgar says 0.4 gram is the initial dose. Repetition of the dose may be called for as the action of the drug disappears in about twenty-five minutes. If no action is secured after the second dose given half an hour after the first, there is no good of further repetition.

Edgar says the extract should have no place in normal labor and its administration should be confined in obstetrics to instances of primary and secondary inertia, to post-partum hemorrhage and Caesarean section.

Theoretically the extract causes intermittent contractions of the uterus, practically with full or repeated doses the contractions approach the tetanic type and clinically must so be reckoned with. Given early in the first stage the extract is equivalent to the use of ergot and must not be used for premature separation of the placenta, fatal compression of the fetus and even uterine rupture have followed its use under these conditions.

In cases presenting a dilated or readily dilatable cervix with inertia existing, without too much resistance the extract renders valuable aid. Edgar observed that the drug acts best at full term in the second stage of labor and is more positive in multiparae than in primiparae. In nineteen cases the drug was used for post-partum hemorrhage and Edgar says the results were disappointing and that he considers its use in these cases unreliable. In Caesarean section the action of the drug was found to be much quicker than ergot. In all cases where it was used to induce labor it failed.

Edgar ends his paper with twenty-four conclusions based on these seventy cases.

PITUITARY EXTRACT IN OBSTETRICAL PRACTICE.

Watson[2] briefly reviews the anatomy and physiology of the pituitary body and then takes up the action of the extract. Watson says that when the extract is given to a woman in labor it quickly causes an increase in the strength of uterine contractions, the duration of contraction is increased and the intervals between the pains shortened. The first contraction he says may be tetanic in character, but they very soon resume their ordinary rhythmic character. Watson says when the drug is given during the first and second stage of labor the results are practically constant, that the results are always most apparent if the pains have been previously feeble occurring at long intervals.

Watson thinks there is little difference in the activity of the preparations now on the market. He advises giving the drug by intramuscular injection and he says no pain follows the injection. Given intravenously pallor, cyanosis, perspiration and a sense of oppression have been reported and therefore is not recommended. Watson also uses as a full dose one cubic centimetre which represents 0.2 gram of the gland substance. There apparently is no cumulative effect of the drug. The effect on the uterus is usually seen within ten minutes and the maximum result is so obtained in from half an hour to an hour and a half after injection. A second injection, Watson says, again stimulates powerful contractions.

Watson is enthusiastic over the action of the drug to accelerate labor when it is already in progress. He says the results are more certain in the second stage than in the first and that the lower the head is in the pelvis the more pronounced is the effect of the drug and that its timely use will save many a forceps operation.

Watson says the use of the extract is indicated in slight contraction of the pelvis, saying, even if forceps should ultimately be required, the more powerful contractions induced, help mould the head and make extraction easier, and that if the drug is going to act it will do so within ten minutes and so no time is lost. He quotes Linzenmeier as urging the use of the extract after pubiotomy. In the earlier part of the first stage the results are not quite so certain, but they are better in multiparae than in primiparae.

Watson says that in severe post-partum hemorrhage he has had no personal experience with it, but in bleeding of minor degree it has produced powerful contractions.

In the induction of labor Watson says there is more or less diversity of opinion but he reports three cases where he used pituitrin; one at the eighth month, one at full term and one three weeks post-term, which were successful. He feels that further trial of the extract is justified. The important point in this type of case he says is to administer a second dose before the effects of the first have passed off.

In placenta praevia, he says, a number of successful results have been recorded, by the extract stimulating strong contractions so that the presenting part is pressed down against the lower uterine segment, and hemorrhage is arrested. When given about two minutes before doing a Caesarean section pituitrin he says has a marked effect in diminishing the loss of blood.

Of the bad effects the drug may have he notes cardiac distress, vertigo, tachycardia, and respiratory difficulty. He suggests that these may have been due to the injection having unknowingly been intravenous. Watson says the drug may set up tonic contractions of the uterus and may cause a spasm of the internal os. The first contraction is usually a prolonged one, one writer having noted pains lasting from four to seventeen minutes. After this first powerful contraction the uterine action is usually normal.

Watson says that these prolonged contractions usually result in a marked slowing of the fetal heart, but that the child is seldom in real danger as the ordinary rhythmic contractions succeed the tonic opening one. One writer reports the death of a child after the injection of 1c.c. of the extract as the result of tetanic contraction, before delivery could be effected with forceps. He quotes Herz as reporting a rupture of the uterus as the result of giving 1 c.c. of pituitrin.

Several writers report spasmodic contractions of the os after the injection of the extract in cases where induction of abortion was desired. One writer reports he had to incise the cervix in one case. Watson says numerous cases have been reported where atony of the uterus followed the termination of the third stage.

The bad effects on the child are due to the prolonged contraction of the uterus.

There is a long bibliography at the close of the article.

ON THE USE OF PITUITARY EXTRACT IN OBSTETRICS.

Harrison[3] begins his article with a short resume of the development of the use of the pituitary extract in obstetrics. He says an examination of the literature shows at least 1650 cases where it has been administered. Harrison says that the use of pituitary extract is not without some danger to the child though danger to the mother seems very slight. He advises that the fetal heart sounds be kept constantly under observation. The danger he says undoubtedly is greatest when the drug is given in the first stage of labor. He states that the majority of observers have found that for the

production of abortion the extract alone is insufficient. He also feels that it is not of any great service in initiating premature labor. He says practically all observers are unanimous in declaring that it is of the greatest value after dilatation of the soft parts and during the expulsion stage of labor where uterine weakness supervenes. Harrison says that of the total number of cases he has found reported there are less than fifty cases of complete failures.

He reports two successful cases in his own practice to illustrate the use of the extract. He also reports two failures, one where the perineum did not relax and the second where the expulsion power of the uterus was not increased. In both these cases forceps delivery was necessary. They are reported without specific data in the most general terms.

Harrison agrees with others that the extract must not be used after the delivery of the child before that of the placenta, because of the danger of tetanus of the uterus and retention. He does not favor its use in post-partum hemorrhage but suggests along with other observers that its use may help the patient to empty her bladder after delivery and that it may prove of use in increasing the milk secretion.

There is a long list of references at the end of the article.

PITUITRIN.

Melville[4] says his purpose in writing this short paper is to direct the attention of every physician who engages in obstetrical practice to the importance of employing pituitary extract in properly indicated conditions. His experience is limited however to eight cases. He says that two of his cases were primiparae and no unusual lacerations of the soft parts were noted. He says it makes little difference whether the os is dilated or not; delivery follows with accuracy and dispatch. He also states no untoward effect has been noticed upon the child.

PITUITARY EXTRACT IN OBSTETRICS.

Lindeman[5] feels that in the use of pituitary extract there is the solution of many a difficult obstetric problem, that by its use many forceps operations can be entirely avoided, that inertia uteri can almost be excluded as an indication for forceps, that many "high forceps operations" will be converted into at least a "medium" and not infrequently into a "low" operation.

He says in the class of cases when the head is on the perineum for some time with infrequent and ineffectual pains, the use of pituitrin will almost invariably enable the patient to deliver herself to her great satisfaction and that of her family and the credit of the physician who has refrained from interference and has employed physiological rather than mechanical means to aid delivery.

Lindeman cautions against using the extract before the cervix is well dilated, for he says it acts sometimes with almost unbelievable violence. As an instance of this violence he mentions a case which occurred in the practice of a colleague when such violent contractions occurred that the patient assumed the position of opisthotonos. But he says no harm was done the mother or child.

In cases where the cervix is not over four fingers dilated he advises only using one half an ampoule (0.05 gm.) at a dose and for an initial dose he says one should never use more than 0.1 gm. If 0.2 or 0.4 gm. be used such violent labor may result that even the administration of chloroform may not control it.

He reports the following cases of his experience with the drug:

In Case 1 pituitrin had no effect.

In Case 2 three injections followed by post-partum hemorrhage and manual removal of the placenta. Patient collapsed and then made an uneventful recovery.

Case 3, one injection without effect. Labor then induced by Voorhees bag and delivery completed by forceps.

Case 4, three injections and labor spontaneously completed. In the convalescence developed severe sepsis but eventually recovered.

In these four cases, pituitrin was used to induce labor and two failures and two successes resulted. The remaining six cases which he reports are of cases where labor had begun. In two cases the cervix was fully dilated. In one case the condition of the cervix was not mentioned and in three it was two to four fingers dilated. In five of these six cases delivery was spontaneously accomplished but in the last forceps delivery was necessary. In this last case he first used a Voorhees bag then seven doses of pituitrin and finally delivered the patient by forceps with manual extraction of the placenta. In one case a contraction ring was found.

In no one of the reports is there mention made whether there were any tears of the cervix or perineum.

Lindeman says the contra-indications for the use of pituitrin are (1) In friable, rigid, or diseased cervices; (2) When there is danger of rupture of the uterus, in cases where fibroids are present or in cases where myomectomies have been done or there is a marked disproportion present. (3) Where there already is a too high blood pressure present. (4) The possible formation of a contraction ring. (5) The danger of asphyxia of the infant. Lindeman feels that this latter danger is not likely to occur unless excessive doses are used.

1. He concludes that the drug is of undoubted value in almost all cases of simple inertia, and fatigue.

2. It is of value occasionally for the induction of labor at or near term.

3. That it seems to be practically devoid of harmful effects and its dangers are few and easily guarded against.

PITUITRIN IN OBSTETRICS.

Litzenberg[6] says pituitrin has passed the first stage of neglect by physicians and is now in the second stage of exploitation and he hopes by a few words of timely warning that he will help in preventing the reaction which must inevitably come by too enthusiastic exploitation. He summarizes the findings of many writers who have had varying results and report absolutely contradictory facts.

Litzenberg reports thirty cases of his own with varying results. The reports are so meagre that a good idea of the cases is not obtained. In sixteen of the cases pituitrin acted promptly, slowly in two and no effect in two. Forceps were required in six cases. In one case tetanic contractions occurred; one child was asphyxiated but soon resuscitated; one extensive laceration due to the violent pains produced. Four times the drug was used in the first stage but only once with satisfactory results. In the twenty-two cases in the second stage seventeen responded promptly.

1. He concludes that pituitrin is a valuable stimulant to uterine contractions.

2. That it will not usually produce abortion.

3. That it will sometimes induce premature labor, but that with an undilated cervix it is not to be recommended.

4. That it is most efficacious during the second stage of labor.

5. That it is of some value during the third stage.

6. That after delivery it is of some value but not better than ergot.

7. That its proven value is limited to the second stage.

8. That the knowledge of its action is still limited and its use is not without danger and so must be used with caution.

In the past few years many reports of the use of preparations from the pituitary gland have appeared. The Germans have written much but with contradictory findings. The several pharmacological houses which have put these preparations on the market write most enthusiastically of its use and from the advertisement of one house the physician would gather that there are no contra-indications for its use and that all the problems in obstetrics will be solved if the extract of the pituitary gland is used. The preceding six articles are culled from the recent literature and show the contradictory reports that physicians give in regard to the use of the extract. Melville's enthusiasm based on an experience of eight cases is characteristic of many articles where the physician's apparent one idea is to obtain a delivery with despatch.

The papers based on many cases with a careful analysis of the cases reported show that the extract is most uncertain in its action and at times, not infrequently, is severe damage done. Premature separation of the placenta, tetanic contractions of the uterus, rupture of the uterus, fatal compression of the fetus, all have been reported as following the injection of the extract and yet more than one writer says it is a safe drug!

The consensus of opinion is that to induce premature labor its action is so unreliable that it should not be used. The more conservative and thoughtful physicians demand that it be not used until the os uteri is fully dilated, that there be absolutely no bony resistance to the delivery and that there be no scar tissue present. When these conditions are fulfilled and uterine pains are insufficient to accomplish delivery, then the use of the extract many times will accomplish surprising results.

If it is given, the physician must stay constantly with the patient for as yet there is no way of determining in any given case what action, if any, will result. As one of the above writers truly states the drug is at present being exploited and because of this exploitation much damage will surely result. The extract is a powerful drug and its indiscriminate use is to be fought. Carefully used it will prove a valuable aid in a small class of cases.

(To be continued.)

Reports of Societies.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of Wednesday, Mar. 11, 1914, at 8.30 p.m.

The President, Dr. William Duffield Robinson, in the chair.

INFLAMMATION OF THE GALL-BLADDER; ITS CAUSES, SYMPTOMS AND RESULTS.

Dr. James Tyson: The paper emphasizes the importance of the early surgical treatment of cholelithiasis, the most important consequence of inflammations of the gall bladder. Perhaps the most common cause of inflammation of the gall bladder is the typhoid bacillus which creeps into the common duct from the bowel. The favoring cause may be gall stones pre-existing in the bladder, or they alone may be sufficient to light up an inflammation. Adhesion of the gall bladder to adjacent viscera is a frequent cause of pain in the right upper quadrant. Cholelithiasis may develop entirely independently of gall bladder inflammation. Predisposing causes are sendentary habits, lack of exercise, tight lacing, child-bearing, abdominal tumors,

excessive use of fatty, starchy and saccharine food. The causal relation of stones in the gall bladder and biliary passages to carcinoma is unquestioned, and I believe that every case of well determined cholelithiasis should be promptly operated upon. Histories of three cases are given in support of this view. Among other terminations of cholelithiasis succeeding upon delay in operation which are scarcely less serious than carcinoma are suppurative cholangitis with involvement of the ducts of the liver and extension to the liver substance or gall bladder, and biliary fistulae. It cannot be denied that associated cancers of the gall bladder may have preceded the cholelithiasis, but there is equal reason to believe that they follow. Medical treatment of cholelithiasis is at best but palliative. In doubtful cases, exploratory operation is justifiable. At present operation upon the gall bladder, if done early, is as free from danger to life as is appendectomy.

THE TREATMENT OF GALL-BLADDER INFECTIONS; WITH A REPORT OF 26 RECENT CASES.

Dr. John H. Gibbon: I have substituted the word "infections" for "gall stones" as we now know that the primary cause of these stones is a microbic infection reaching the gall bladder either through the blood or directly through the bile passages from the intestine. The object of the paper is to consider operative indications, present some of the pathological complications arising when these indications are not heeded, and to say something about the post-operative mortality and its causes. The basis of the paper is a series of 26 gall bladder cases upon which I have operated during the past six months. The figures, though small, illustrate every point I would make. If one feels warranted in making a diagnosis of gall-stones or gall-bladder infection, one should also feel warranted in advising operation unless there be some definite contraindication. To await serious symptoms is comparable to awaiting glandular metastasis and malignant cachexia before making a diagnosis of cancer. The earliest and most persistent symptom of gall bladder infection is what the patient calls "indigestion" or "distention" in the upper abdomen, coming on especially at night and without any definite relation to the taking of food. Jaundice is not essential to a diagnosis; about 80% of operated gall-stone cases have not had this symptom. Gall-bladder symptoms may result also from other causes than the presence of stones and which demand operation.

In the present series there were two cases of acute cholecystitis without stone and three of chronic cholecystitis without stone. In my opinion both patients would have later developed stones had they not been operated upon. The brief series of cases here reported includes three cases of acute gangrenous cholecystitis, all of which recovered; two cases of acute cholecystitis without stone, one developing two weeks after typhoid fever, eight cases of stones in the common duct, one of stone in the ampulla of Vater requiring duodenotomy; one of calcification of the gall bladder, one of abscess formation in the liver and spleen, one of subdiaphragmatic abscess two weeks after operation in a case of acute cholangitis due to stones in the common duct, one of cirrhosis of the liver, one of stones ulcerating into the colon, twenty cases of stones in the gall-bladder alone or associated with some of the enumerated complications, and two cases of cancer of the gall bladder. The greatest number of stones, 771, was found in one of the malignant cases. In the cases in which the duration of symptoms is given the average is over six years. The youngest patient was 19 and the oldest 69 years of age. There were 5 deaths, all of which occurred in very ill patients. Regarding the probability of gall stones reforming after operation, I believe that if all are removed and the gall passages properly drained for about two weeks that recurrence is extremely rare.

THE ROENTGEN RAYS IN THE DIAGNOSIS OF GALL STONES AND CHOLECYSTITIS AN IMPROVEMENT IN TECHNIC.

Dr. George E. Pfahler: The improvement in technic consists, in addition to the special technic described by the author in 1910, in the use of (1) a second position by which the rays are directed through the substance of the liver, thereby eliminating the irregular shadow produced by the bowel and its contents; (2) that which is more important, the inflation of the colon, and at times of the stomach, by air, for the purpose of more definitely outlining the gall-bladder and under surface of the liver.

The lantern demonstration consists of a series of slides showing the borders of the liver, gall-bladder and spleen; also a series of 20 cases showing gall-stones, which were confirmed by operation.

As a result of these studies the following conclusions are drawn:—

1. Gall-stones can be shown only when they are composed of a substance of greater or less density than the surrounding tissue. This will usually mean that they must contain some lime salts, though this quantity may be small.

2. My records show positive findings in 74 per cent., but I believe that in general, one cannot count upon more than 50% being demonstrable. I believe a negative diagnosis at present has no value.

3. It is possible that with this improved technic, when we find the gall-bladder small, and still find no stone, it may become of some value in negative diagnosis.

4. The estimation of the value of this method of diagnosis must be based only upon the work of Roentgenologists who have mastered a good technic, and who are thorough in their work.

5. Definite information will be obtained only by continued coöperation of the surgeon and Roentgenologist.

6. I believe that in the future we shall obtain valuable information concerning the liver and spleen by the Roentgen method described.

DISCUSSION.

Dr. H. A. Hare (Discussion read by Dr. William E. Hughes in the absence of Dr. Hare):

I believe the following statements of Anderson express excellent views and are fairly warranted by our present knowledge:—

1. That while surgical procedure is frequently the best and often the only means offering a chance of relief, its advocacy, based on certainty of cure and assurance of non-recurrence, is not borne out by results.

2. That the main object of treatment is the relief of the infection and inflammatory changes, and not merely the removal of gall-stones. So long as

there is no recurrence of the inflammatory attacks, there will be no attack of gall-stones.

3. That recovery not infrequently occurs under non-operative treatment, especially in early and mild cases, and particularly after first attacks, before serious local damage has been produced by the infection.

4. Medical treatment should be given a fair trial in all cases where the patient's physical condition does not warrant operation, and with the numerous patients who refuse operation. In many such cases Anderson asserts he has seen complete and permanent recovery from all symptoms of the disease.

5. Medical treatment is indicated in many cases as a preliminary to operation, and in order to allow the acute infection to subside as far as possible.

6. Medical treatment is indicated in all cases after operation to allow of complete subsidence of the infection, and if possible, to prevent re-infection and recurrence.

7. Anderson believes that it would make for clearness of thinking and give definiteness to therapeutic aims if we adopted the suggestion of Naunyn and gave up the term cholelithiasis and classified these various infections of the biliary passages and cholangitis with such qualifiying terms as simple, catarrhal, suppurative, gangrenous, calculous, etc., according to the condition present in the particular case.

The paroxysmal nature of the symptoms, and the relief of pain temporarily upon eating are characteristics very suggestive in diagnosis. Probably the one symptom which is never lacking is that of indigestion.

DR. THOMAS R. NEILSON: I think we cannot emphasize too strongly the danger of delaying operation with the diagnosis of cholecystitis fairly made. Although the attacks may subside there is always the danger of recurrence and of the development of malignant disease. The symptom of indigestion as indicative of a chronic lesion of the gall-bladder is important, and sometimes the only one upon which a diagnosis can be made. At operation pericholecystitis is one of the commonest associated conditions, and for this nothing but operation would be of avail.

DR. W. WAYNE BABCOCK: I would emphasize the value of local anesthesia in certain types of gall-bladder disease.

Personally, he never advises strongly against operation in any case, unless it is definitely contra-indicated, but, after explaining the possibility of failure, and that operation may eventually be required, Anderson does not hesitate in early and mild cases, and especially after first attacks, to give medical treatment a thorough trial, and has found that in many instances, excellent and permanent results have been obtained.

To which I would add that occasionally we see cases die after operation that would have lived many weeks if they had been let alone surgically. Where there are evidences of septic trouble or gangrene, operation is, of course, imperative.

DR. WILLIAM E. HUGHES: It is important to recognize the existence of gall-stones because, while they may lie quiescent through the normal life of the patient, they are there and are a possible source of trouble. Nine times out of ten in cases in which my attention has been called to "gall-stones" collected from the feces they have proved to be not gall-stones, but foreign matter.

We should realize that gall-stones represent a terminal condition. The patient may have had few symptoms for five or twenty years, but finally develops an acute condition. In such a case it would have been much better to try to prevent such an outcome by early operation. It is interesting to note what other symptoms may follow gall-bladder disease. Most surgeons have seen cases in which the most surprising results have followed operation upon the gall-bladder. Arthritis deformans sometimes disappears after a gall-bladder operation. In a patient with the tic douloureux who developed gall-bladder disease the pain of the former condition disappeared after removal of the pus and gall-stones, We know that neuritis may result from gall-bladder infection. There are also conditions in the intestinal tract and other remote conditions due to intoxication or passage of the bacteria to these parts of the body. It seems to me that within the next two or three years we are going to revise our conceptions of intestinal indigestion.

DR. ROBERT N. WILLSON: I have seen more than one case of cholangitis and also gall-stone cases of necessity treated medically when the surgeon could not be reached. In such cases the symptoms have disappeared with the emptying of the intestinal tract. In gall-stone cases I have seen more than one case carried over year after year simply because the patient absolutely refused operation.

DR. GIBBON, closing: As to the archaic conclusions of Anderson which Dr. Hare left—I would have left them, too, I think—I am sorry Dr. Hare is not here to defend them.

What Dr. Pfahler has shown us is of the greatest value and promises a great deal of help. Dr. Pfahler said that negative findings do not mean that the patient has not stones. It also does not mean that the patient has not an infected gall-bladder, which, as Dr. Babcock says, gives rise to all the trouble. I feel that the interpretation of the x-ray plate must be made by an expert as well as the x-ray picture itself. I regret that the treatment in Dr. Anderson's cases was not given. There are a lot of cases apparently cured which are not really cured.

HARTFORD MEDICAL SOCIETY.

At a meeting of the Society, held April 6, DR. F. C. WOOD, Professor of Clinical Pathology, Columbia University and Director of Cancer Research, George Crocker Special Research Fund, read a paper, illustrated by lantern slides on the subject

OUR KNOWLEDGE OF CANCER.

Dr. Wood gave a brief historical resumé, showing that while cancer had been recognized by the Hindus, Egyptians, and Greeks, from the earliest periods, and had been carefully studied since then, a limit had been reached for clinical investigation of the disease, and that nothing regarding the cause of cancer had been learned. About ten years ago the use of animal transplantation, first introduced by Jensen, placed in the hands of laboratory experimenters a powerful means of approach to the unsolved question, and more had been learned as to the cause of cancer in these ten years by laboratory investigations than in the preceding thirty-five centuries. Dr. Wood gave a short account of the vari-

ous discoveries which had been made by means of experiments on animals; some of these were of biological importance merely, while others had a direct application to the human race. He spoke of the question of hereditary transmission of cancer in mice, but stated that this occurred only in certain races, in which there had been an intense concentration of cancerous ancestry, and said that it would require two or three hundred years of inbreeding of cancerous human beings to duplicate the results obtained with the mice. Such a concentration could not occur under ordinary conditions in man, and it was, therefore, doubtful that heredity played an important part in the cause of cancer. He also pointed out that cancer is not contagious; that cancer can not be transmitted from animals to man; and that cancer houses and cancer districts do not indicate either contagion or hereditary transmission, but are due to accidental groupings which can be explained by the laws of probability. He illustrated the availability of animals for the study of cancer by detailing some of his own results in treating cancer in mice with radium, the effect being as unfavorable in animals with malignant tumors as it is in man. He strongly urged the wider education of the profession in the matter of the early diagnosis of cancer, preferably by the microscope, and stated that in his opinion nothing but early surgery was of any benefit in the cure of cancer.

Book Reviews.

Text-Book of General Pathology. Edited by M. S. PEMBREY AND J. RITCHIE. New York: Longmans, Green and Company. London: Edward Arnold. 1913.

This book hardly lives up to its title of a text-book of general pathology. It consists of twenty chapters, written by different authors.

1. Introduction. By Ritchie and Pembrey.
2. Pathology of the Blood. By A. E. Boycott.
3. Information. By Ainley Walker.
4. Infection. By Ainley Walker.
5. Immunity. By C. H. Browning.
6. Degeneration, Necrosis and Calcification. By J. Lorrain Smith.
7. Hypertrophy and Atrophy. By J. Ritchie.
8. Tumors. By J. Ritchie.
9. Pathology of the Circulation. By A. E. Boycott.
10. The Nervous System. By F. W. Mott and S. V. Sewell.
11. Respiration. By J. S. Haldane.
12. Physiology and Pathology of Temperature. By M. S. Pembrey.
13. Pathology of Digestion. By A. F. Hertz.
14. Metabolism. By M. S. Pembrey.
15. Metabolic Disturbances Which Result from Hepatic Disease. By A. E. Garrod.
16. Anomalies of Metabolism. By A. E. Garrod.
17. Diabetes Mellitus and Some Other Changes in Carbohydrate Metabolism. By A. P. Beddard.
18. Gout. By I. Walker Hall.
19. Physiology and Pathology of the Kidney. By J. H. Ryffel.
20. Death. By J. Ritchie.

The reputations of the authors indicate the excellence of these chapters, most of which are very interestingly written. The physiological viewpoint is maintained by each author. The book contains a very few illustrations, and these few are of poor quality. The book can hardly be recommended as a student's text-book, but can be endorsed heartily for collateral reading in connection with a course in pathology or for graduates who wish to review their pathology or to get a knowledge of its recent advances.

Pathologisch-Anatomisches Praktikum. Für Studierende and Ärzte. Von PROFESSOR DR. MED. RICHARD OESTREICH. Urban and Schwarzenberg. 1913.

A German quiz compend in pathology, modeled after similar compends in anatomy. Possibly of use in preparing for examinations, but not where the examinations are intelligently given.

Practical Bacteriology, Microbiology and Serum Therapy. (Medical and Veterinary). A Text-*Book for Laboratory Use.* By DR. A. BESSON. Translated and adapted from the Fifth French Edition by H. J. HUTCHENS, D. S. O. pp. 892. New York: Longmans, Green & Co. 1913.

This is the most complete reference book of its size in bacteriology. It is thoroughly up-to-date on most subjects, and contains directions and formulae for practically every known bacteriological procedure. The principal bacteria are concisely and well described. The book also includes a section on spirochaetes and protozoa pathogenic for man and animals. The inclusion of Veterinary Bacteriology enhances the value of the book materially for the laboratory worker. The absence of theoretical discussions perhaps detracts from its value as a student's text-book. It is a book that has proved very valuable to laboratory workers, as a handy reference volume, and is the best book of this sort, of which the reviewer has knowledge. It makes an admirable text-book for advanced students. The one serious criticism is the failure to give the references to the different authors quoted.

THE BOSTON

Medical and Surgical Journal

THURSDAY, MAY 7, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE ADVANTAGES OF THE DE RIBES BAG IN OBSTETRICS.

IT may be asserted with truth that with the advent of Barnes' dilators a new era was inaugurated in obstetrical practice, and it may also be truthfully stated that even now the many practical benefits to be derived from the method of procedure which this device exemplified are not at all adequately appreciated by the great mass of practitioners. The artificial dilatation of the os uteri, in imitation of its natural opening in labor, was first practised by Klüg, by means of the sponge tent; but this method had the disadvantage of occupying an indefinite time, the irritation produced was often painful and annoying, and, worse still, the tent sometimes became a source of infection. The Barnes rubber dilators therefore constituted a very marked advance. These, however, were not without their disadvantages, and from time to time various improvements have been introduced in the means for the production of dilatation, until we now have at our command one superior in every way to its predecessors. This is the hydrostatic dilator known as the modified Champetier de Ribes bag. For those not familiar with it, it may be stated that the de Ribes bags, of five sizes, are conical in shape and made of canvas (and hence inelastic), covered with rubber, and the stem, through which normal salt solution or sterile water is injected into the bag, is very strongly attached to the apex; making it possible to make moderate traction if desired.

The largest field of application for the bags is naturally in the induction of labor, and in 1912 Dr. George L. Brodhead, professor of obstetrics in the New York Post-Graduate Medical School, who is an enthusiastic advocate of their use, published in the *American Journal of Obstetrics* a series of 139 cases in which they were employed for this purpose, and in which the results were for the most part extremely gratifying. In 90% of these, labor was induced by the use of not more than two bags, while in nearly 70% one bag was sufficient. Anesthesia for bag introduction was usually unnecessary, as shown by the fact that an anesthetic was used in only 14% of private cases and 16.6% of all cases, including hospital cases, where it was deemed advisable for clinical purposes. The two chief causes for which labor was induced were contracted pelvis (41 cases) and toxemia, including albuminuria, nephritis and eclampsia (27 cases). In seven of the cases a change in the fetal position occurred after bag introduction, and while except in one instance the change in presentation made no difference in the outcome, the possibility of this accident should be kept constantly in mind when one is using the bag method.

At a recent meeting of the Medical Association of the Greater City of New York (before which also his first paper was presented), Dr. Brodhead read a second paper on the use of the modified de Ribes bag in obstetrics, and in this he expressed the conviction that in this device we were in possession of such a valuable aid in obstetric work that we might well consider whether more extensive application could not be made of it. Although it has now been in use for a considerable number of years, it is a matter of surprise to him that greater advantage has not been taken by the profession at large of a method at once so simple and of such great value. In addition to the well-known indications for the interruption of pregnancy, he has found the bag of great service in patients where the child is large and the pelvis normal or slightly undersized. Again, he believes that in a patient at term, especially a primipara, if pains have not begun within twenty-four hours after the premature rupture of the membranes, labor should be induced with the bag. Furthermore, in primiparae especially, the child is sometimes found to be too large to pass through the pelvis, and in his opinion many children now lost might be saved by the interruption of preg-

nancy. In the treatment of antepartum eclampsia he advises that medical treatment (in which he lays stress on the value of venesection in selected cases and of veratrum more generally) should be carried out as vigorously as possible, but also that pregnancy should be terminated by the induction of labor. Inasmuch as pregnancy is the direct cause of the eclampsia, he is convinced that the uterus should be emptied within a reasonable time, not by a radical procedure, such as vaginal or abdominal section, but by the slower and more physiological method. For this purpose he combines the use of the bougie, or rectal tube, with that of the bag. In this class of cases, as so many others, the latter affords an invaluable aid in the treatment, but the condition is so urgent that its employment should be supplemented by the introduction of the rectal tube, thus making the induction of labor more certain. Whatever result the ultimate statistics of the treatment by section may show, he believes that in the hands of the general practitioner the induction of labor, combined with vigorous medical treatment, will continue to give the best results. When eclampsia develops in the early part of the first stage of labor, the method of choice is the use of the bag for the dilatation of the cervix, and in the latter part of the first stage, the application of forceps, podalic version, or, when the child is dead, craniotomy. Vaginal section is indicated, if at all, in those cases in which the cervix is very rigid and where the bag and bougie have failed, after a reasonable time, to effect softening and dilatation. In a primipara at or near term, with a small, rigid vagina and a contracted pelvis, abdominal Cesarian section would be the operation of choice.

In a considerable number of conditions there is, in Dr. Brodhead's opinion, no method of procedure comparable in results to the use of the bag. For marginal placenta previa it offers an almost ideal resource. Here the problem is how to secure full dilatation of the cervix with the least violence and loss of blood, while in no way injuring the child. One of the larger sizes should be employed, and after the cervix has been well dilated version can be performed with much greater ease and with better results for both mother and child. In central placenta previa at term, and in the marginal variety at term in primiparae, abdominal Cesarian section in the hands of competent operators, with proper surroundings, will undoubtedly give the best results; but, on the other hand, Cesarian section as a routine procedure would give a much larger mortality than the conservative treatment with the bag and podalic version. So-called accidental hemorrhage often demands the interruption of pregnancy, and here, again, the bag may offer a solution of the problem. In this instance, however, the source of bleeding is too high up to be influenced by it; so that where the hemorrhage is very profuse, or continues moderately with the bag in place, some other method of procedure is indicated, the choice lying between manual dilatation, followed by forceps or version, and vaginal or abdominal section. Finally, the bag is useful in cases of tedious labor, especially in primiparae with breech presentation; and in prolonged first stage where the patient, after many hours of suffering, has made but little progress, its introduction will frequently cause the pains to become more effective. In breech cases the breech of the child is a very poor dilator, and when the labor is proceeding very slowly there is no better method of expediting matters than by means of the bag.

MEDICAL ASPECTS OF THE SITUATION IN MEXICO.

WITHOUT actual declaration of war there has already been American bloodshed in Mexico. Vera Cruz was seized on April 22 by United States marines in conjunction with the naval fleet, and is now occupied by American troops. On the following day, the medical department of the military government began clearing the wreckage of the local Naval Academy, which was destroyed by shells during the bombardment. Much of the clothing and other contents of the building have been transferred to the Charity Hospital, where the wounded will be cared for.

Provisions for nursing in field and base hospitals are being made by the American Red Cross, which on April 23 issued the following statement:—

"In view of the Mexican situation and the duties and responsibilities that may devolve upon the American Red Cross, the people of the United States are hereby informed that the Red Cross is prepared for whatever service the Gov-

ernment may require of it as the society created by congress to furnish volunteer aid to the sick and wounded of armies in time of war and to serve as a medium of communication between the people of the United States and their army and navy.

"Attention is called to the fact that under the provisions of the treaty of Geneva, by presidential proclamation any other society desiring to render similar assistance can do so only through the American National Red Cross. Immediate preparations for fulfilling these duties are imperative. The war relief board meets April 30 to adopt a definite plan of action. This will involve heavy expenditures and the Red Cross relies upon the public for generous contributions to enable it to meet these demands. Contributions may be sent to local or state treasurers or to the Red Cross, Washington, D. C."

As yet there has been no outbreak of disease among American troops in Mexico. Probably typhus is their greatest risk, since it is endemic over the Mexican plateau, where it is locally known as *tabardillo*. There is a great deal of typhus in Mexico City, but none along the seacoast. There the disease most to be dreaded is yellow fever.

At Vera Cruz every precaution is being taken against the outbreak of any infection. One case of smallpox was discovered among refugees in the city, and extensive vaccination of nonimmunes has been instituted. Over a thousand American refugees have arrived at Galveston, Tex., and report from that city on April 27 states that three cases of small-pox have occurred among those aboard the battleship *Connecticut*. Careful quarantine has been established.

At the present writing, the likelihood of mediation makes further hostilities seem improbable. In the event of their occurring, however, every preparation has been made by the army medical corps to establish hospitals in the rear of troops advancing inland. The plan of distribution of these hospitals will be as follows:—

"Each division, which is made up of four brigades, will have four field hospitals. In each hospital are 108 beds. In the rear of the field hospitals will be an evacuation hospital, which will hold twice as many beds as a field hospital. Behind the evacuation hospital, fifty or one hundred miles—it depends on the position—will be the base hospital. To each field hospital are five surgeons, to each ambulance corps three surgeons, to each regiment four medical officers and twenty-two members of a hospital corps, and to each division a chief surgeon and a chief sanitary inspector."

On the part of the Mexicans there is said to be considerable difference in degree of medical efficiency. The medical department of General Villa's constitutionalist army is in command of Dr. Andres Villareial, a graduate of Johns Hopkins. It has a well equipped hospital train, capable of caring for 1400 patients for 40 days, and a modern field hospital with an abundance of trained nurses. The medical department of General Huerta's federal army, on the contrary is poorly officered, ill-equipped, and inefficient.

In the event of war, the American loss from disease should be proportionally the lowest that has ever been observed. In the first Mexican War, of 1848, the total American loss from disease was 6408, while the loss from wounds received in battle was about 5000.

MEDICAL LEGISLATION. REORGANIZATION OF THE STATE BOARD OF HEALTH.

Governor Walsh, with the assistance of men eminent in public health work both in the state and in the nation, has drawn up a bill to create a state department of health and to modify the existing health laws in Massachusetts. This bill conforms closely to the suggestions made in the Governor's inaugural message and also to the general principles of certain recommendations made previously in these columns. The Governor's bill has the enthusiastic endorsement of a considerable body of medical men with whom he has been in consultation.

The bill calls for a single, highly paid commissioner of health with an advisory unpaid public health council. The Governor is wise enough to appreciate that mere organization, though important, is but the vehicle for the introduction and execution of health measures. Consequently his bill gives somewhat wider and better defined powers to the health department than the state board of health has enjoyed in the past.

Since the time has apparently come for a reorganization of the state health department, it is very gratifying that Governor Walsh has risen to the opportunity of attempting to create as good a department as is possible under the circumstances. The broad minded manner in which he has obtained the advice of eminent ex-

perts is particularly commendable. This bill, now in somewhat rough form, will be discussed in detail in subsequent issues of the JOURNAL. From present indications the bill should receive the hearty support of the medical profession.

MEDICAL NOTES.

ERADICATION OF UNCINARIASIS IN CENTRAL AND SOUTH AMERICA.—The Rockefeller Commission for the Eradication of Hookworm Disease, it is announced, is to extend its field of activity into Central and South America; and Dr. Joseph H. White, of the United States Public Health Service, is to superintend this work.

PNEUMONIC PLAGUE IN TOKYO.—Report from Tokyo, Japan, on April 24, states that pneumonic plague is at present epidemic in that city, and that many deaths from it have occurred.

BUBONIC PLAGUE IN CUBA.—Two more cases of bubonic plague were reported in Cuba on April 22, one in Havana, the other at Artemisa, a small neighboring town. This makes a total of 12 cases since the beginning of the outbreak several weeks ago.

INTERNATIONAL CONGRESS ON CHILD WELFARE.—The third International Congress on Child Welfare was held from April 23 to 25, inclusive, at Washington, D. C. At the opening session, Miss Julia C. Lathrop described the work of the children's bureau of the United States department of labor, and Mrs. Frederick Schoff, of Philadelphia, reported the work of the national congress of mothers and parent-teachers, of which she was president. On April 24, Professor E. A. Kirkpatrick, of Fitchburg, Mass., read a paper on "Training Children in Financial Responsibility"; and Dr. Helen C. Putnam, of Providence, R. I., on "Twentieth Century Motherhood." Mr. Nathan Straus of New York described the work of the milk stations in that city, whose infant mortality under five years has fallen from 96.5 per 1000 in 1891 to 37.3 per 1000 in 1913.

BOSTON AND NEW ENGLAND.

MEASLES IN NEWPORT BARRACKS.—Report from Newport, R. I., on April 26 states that 5 cases of measles have recently occurred among men in the naval training station barracks at that port.

A CENTENARIAN.—Patrick Welch, who died at Brighton, Mass., on April 23, is said to have been born early in 1814 in Ireland. He migrated as a boy to Montreal, and thence came to Brighton in 1842. He is survived by five of his eleven children. He attributed his protracted longevity and good health to his lifelong habit of total abstinence from tobacco and alcoholic liquors.

FITCHBURG BOARD OF HEALTH.—The recently published twenty-fourth annual report of the board of health of the city of Fitchburg, Mass., records the activities of that body for the calendar year 1913. It contains also the reports of the agent of the board, the bacteriologist, the school physicians, the school nurse, the inspectors of milk, plumbing, meats, provisions, and slaughtering. The total death-rate of the city was only 13.38 per 1000 inhabitants, and the infant death-rate, under one year, was only 103.3 per 1000 births.

VISIT OF FOREIGN SURGEONS TO BOSTON.—On Monday and Tuesday of last week, April 27 and 28, a number of foreign members of the International Surgical Association, whose fourth triennial convention has recently been held in New York, visited Boston as guests of the local members of the American Surgical Association. Operations, demonstrations and receptions were held at the various hospitals, at the Harvard Medical School, and at Harvard College, Cambridge. On Monday evening a dinner was given at the Copley-Plaza Hotel.

A MEDICAL MEMORIAL TO DICKENS.—On April 29 the All Around Dickens Club, of Boston, celebrated its twentieth anniversary by dedicating a free bed in memory of Charles Dickens at the new Children's Hospital.

HOSPITAL BEQUESTS.—The will of the late Eliza E. Hobbs, of Waltham, Mass., which was filed on April 25 at the Middlesex registry of probate, contains bequests of $5000 to the Waltham Hospital, $1000 each to the Waltham Baby Hospital and the Waltham Training School for Nurses, and $500 to the Waltham District Nurses' Association.

The will of the late Benjamin F. Keith, of Boston, which was filed on April 25, in the Norfolk Probate Court at Dedham, Mass., contains a bequest of $5000 to the Boston Floating Hospital.

Cases of infectious diseases reported to the Boston Board of Health for the week ending April 28, 1914: Diphtheria, 52; scarlatina, 101, of which 16 were non-residents; typhoid fever, 3; measles, 89, of which 2 were non-residents; tuberculosis, 51.

The death-rate of the reported deaths for the week was 17.22.

NEW YORK.

Pure Food Investigation.—At a meeting of the recently organized food and drugs department of the National Civic Federation, held on April 26, an investigation, embracing the entire country, into the methods of handling products as regards pure food principles, cleanliness, right labeling, and honest advertising, was decided upon, in order to determine the lines on which the federation can work to the best advantage in securing pure foods and drugs for the American people. The chairman of the committee which has charge of the proposed investigation is Vincent Astor, and among the members are Dr. C. A. Alsberg, chief of the bureau of chemistry, United States Department of Agriculture; Dr. S. S. Goldwater, commissioner of health, New York City; and J. H. Wallis, president of the Association of American Dairy, Food and Drug Officials. The plan of operations includes the sending out of a list of questions to federal and state food, drug and dairy commissioners, state and municipal health officials, professors of chemistry in universities and colleges, agricultural chemists, and representative dealers in foods and drugs throughout the country.

Election of Dr. Park.—On April 27 Dr. William Hallock Park, director of the research laboratories of the New York City Health Department, and a pathologist and bacteriologist of international reputation, was unanimously elected by the Council of New York University dean of the University and Bellevue Hospital Medical College, to succeed the late Dr. Egbert Le Fevre. For a number of years Dr. Park has been professor of bacteriology and hygiene in the college, and he was recommended for the position of dean by Prof. William H. Welch of Johns Hopkins University, Dr. Simon Flexner of the Rockefeller Institute, and other high authorities.

Death from Typhus Fever.—On April 27 the first death occurred among the typhus fever patients at Swinburne Island, Quarantine Station. The patient was a Greek who had embarked on the steamer *Madonna* at Naples. Since January 7, 19 typhus patients have been received at Quarantine, and all the cases are stated to have occurred among soldiers who had been in the Balkan wars.

Honor for Dr. Flexner.—Dr. Simon Flexner, director of the Rockefeller Institute, has been notified by the French ambassador at Washington that the Cross of Chevalier of the Legion of Honor has been conferred upon him by President Poincaré. This honor has been bestowed, it is stated, in recognition of the services rendered to medical science by Dr. Flexner through his own discoveries and his admirable administration of the institute. In the award special mention is made of the assistance given to France, at the time of the epidemic of cerebrospinal meningitis there, by the sending to the Pasteur Institute in Paris of a supply of the new anti-meningitis serum, which was successfully employed in combating the disease.

Award of Seaman Medal.—On April 28 the Louis Livingston Seaman medal of the American Museum of Safety was presented to Surgeon General William C. Gorgas, in recognition of his great sanitary work in the Panama Canal Zone. The speech of presentation was made by Prof. F. H. Hutton of Columbia University, and other speakers on the occasion were Arthur Williams, president of the museum, Dr. N. E. Ditman, and Dr. Seaman, the donor of the medal, as well as Gen. Gorgas himself.

Appointment of Dr. Janeway.—It is announced that Dr. Theodore C. Janeway, Bard professor of the practice of medicine in Columbia University, has accepted the professorship of medicine in Johns Hopkins University, Baltimore, recently offered him, under the full time basis made possible by the gift to the University of $1,500,000 by the General Education Board. It is stated that Dr. Llewellys F. Barker, who succeeded Sir William Osler in the chair of

medicine, was unable to remain in the position under the new conditions, but will continue his service at the Johns Hopkins Hospital.

DEATH-RATE FOR WEEK ENDING APRIL 25, 1914.—There were 1637 deaths and a death-rate of 15.30 per 1000 of the population reported during the past week as against 1677 deaths and a rate of 16.28 for the corresponding week in 1913, a decrease in the absolute number of deaths of 40 and in the rate of .98 of a point, a relative decrease of 105 deaths. The following causes showed material deductions: Measles, diphtheria and croup, whooping cough, diarrheal diseases under five years of age, acute bronchitis, lobar and broncho-pneumonia, pulmonary tuberculosis, Bright's disease and nephritis. The causes showing an increased mortality were scarlet fever (the mortality from this cause being double that of the corresponding week of last year), forms of tuberculosis other than pulmonary, diseases of the nervous system and violence. Viewed from the point of age grouping, there were 28 less deaths of infants under one year, 17 less between one and five years of age, 25 less between five and sixty-five years of age, and 30 more over the age of 65. The borough of Richmond showed the highest mortality, due in great measure to the unfavorable distribution of the age grouping of the population and the presence of several large institutions, the inmates of which are chiefly non-residents. The second highest mortality was that of the borough of Manhattan, then followed borough of Brooklyn, borough of Queens and the borough of The Bronx in the order mentioned. The death-rate for the first 17 weeks of this year was 15.46 per 1000 of the population as against a rate of 15.68 during the corresponding week in 1913, a decrease of .22 of a point.

A GOOD VETO.—Report from Albany on April 25 announces that Governor Glynn has vetoed the bill, recently passed by the state legislature, permitting unlicensed practise by Christian Scientists, chiropractors, and naturopathists. In his veto message the Governor said in part:—

"This bill is advocated by Christian Scientists. If it simply allowed Christian Science healers to practise among the followers of Christian Science, there might not be serious objection to it; but it opens the gates to all kinds of medical pretenders, who as a matter of fact 'administer to or treat the sick or suffering without the use of any drug or material remedy' and who, if this bill were approved, would swarm across our borders and pretend to practise medicine upon our citizens."

RESEARCH WORK IN GENETICS.—At the meeting of the Eugenic Section of the American Breeders' Association at Palmer, Mass., in 1911, a research committee was appointed "to study and to report on the best practical means of cutting off the defective germ-plasm in the American population. This committee has recently issued from Cold Spring Harbor, Long Island, the headquarters of the Eugenics Record Office, two bulletins, one (No. 10A) on "the scope of the committee's work," and one (No. 10B) on "the legal, legislative and administrative aspects of sterilization." The committee is still working and no doubt other bulletins will follow. Meantime the organization has changed its name to the American Genetic Association.

NEW YORK STATE MEDICAL SOCIETY.—At the 108th annual meeting of the Medical Society of the State of New York, held in New York Apr. 28-30, the following officers were elected: President, Dr. Grover Dende of Buffalo; first vice-president, Dr. Myron B. Palmer of Rochester; second vice-president, Dr. Samuel W. S. Toms of Nyack; third vice-president, Dr. Robert M. Elliott of Willard. Dr. W. R. Townsend of New York was reëlected secretary, and Dr Alexander Lambert of New York, treasurer. The annual dinner of the society was given at the Hotel Astor on April 29, and was attended by more than eight hundred physicians. The toastmaster was the retiring president, Dr. William F. Campbell of Brooklyn, and among the speakers was Dr. Wilfred Grenfell of Labrador.

1. Harris describes six very distinct cases in which a fold or band passed from the gall bladder down over and constricting the second part of the duodenum and produced a definite set of symptoms resembling those of duodenal ulcer. These cases were all permanently relieved by division of this band at operation. Harris describes this band as the abnormal remains of the caudal edge of the ventral mesogastrium, or by some called the great omentum hepatocolicum.

2. Dyas' use of a large dental burr in drilling out diseased bone in osteomyelitis seems like a very rational procedure and a decided advance in technic, as the operator can work more rapidly and at the same time with less danger of damaging normal bone and leaves no rough spicules or ragged edges.

3. Hare, after having operated on twenty-five cases of aneurysm by wiring and electrolysis, claims that this is the only method sure to give relief in aortic cases. He does not consider it a dangerous operation. He uses a yellow gold wire.

5. Macleod's article is not suited for abstracting, but is a very thorough review of experimental work on glycosuria.

7. Craig finds marked variations in the strength of the Wassermann reaction from day to day in untreated syphilitic cases and believes therefore justly that a single negative or doubtful Wassermann reaction is of no value in excluding syphilis. He goes into some detail to explain the reasons for this variation. The paper is a suggestive one.

8. Kilgore found the luetin test of practical value in a few cases of late syphilis (4 out of 36), in which it was positive when the Wassermann was negative.

12. Eising finds evidence that prostatectomy and hysterectomy in diabetes of long duration is occasionally followed by subsidence or total disappearance of the sugar output. No plausible explanation is at hand. [E. H. R.]

THE LANCET.

APRIL 4, 1914.

1. OLIVER, T. *Medico-Social Problems from an Insurance Point of View.*
2. *WHITEHOUSE, H. B. *Hunterian Lecture on the Physiology and Pathology of Uterine Hemorrhage. Concluded.*

4. *DAVIES, H. M. *The Operative Treatment of Pulmonary Tuberculosis.*
5. *JORDAN, A. C. *Some Points in the Diagnosis of Pulmonary Tuberculosis by the X-rays.*
6. COOPER, G. *A Case of Thoracic Aneurysm of Unusual Size.*
7. KEILLER, D. W. *Extrathoracic Aneurysm of the Transverse Arch of the Aorta.*

2. In this second Hunterian Lecture, Whitehouse discusses pathological uterine hemorrhage, taking up the factors involved in excessive bleeding, the relation of the endometrium to this, and the importance of investigating the menstrual discharge. He then takes up hemorrhage at puberty and at the menopause, and then considers hemorrhage in relation with organic disease of the internal sexual organs and the treatment of such conditions.

3. Among the causes for the failure of vaccine therapy, Crofton mentions (1) failure of patient to react (2) failure to diagnose the infecting organisms, (3) incomplete immunization, (4) failure to give the doses at the proper intervals.

4. This is a very brief discussion of artificial pneumothorax in pulmonary tuberculosis, with a mention of other more radical measures.

5. Jordan, in his usual interesting, but somewhat over-enthusiastic view, urges the x-ray as the only means of making the true early diagnosis of phthisis, and argues in favor of this "peribronchial phthisis." Early diagnosis has been kept back for years, he states, because it has been the custom to use and depend on the stethoscope and to look at the apices for the initial lesion. (His remarks applied to children are of interest and value; in adults they are interesting, if true.—J. B. H.). [J. B. H.]

BRITISH MEDICAL JOURNAL.

APRIL 4, 1914.

1. RUSSELL, R. H. *Lister: The Laboratory and the Bedside.*
2. *SIMSON, H. J. F., AND BERNSTEIN, J. M. *Remarks on Infection by B. Coli in the Puerperium and on the Infective Conditions of Pregnancy.*
3. CASTELLANI, A., AND PHILIP, M. *Plague in Ceylon.*

6. TIBBLES, S. G. *Two Cases of Ocular Disease Associated with Pyorrhea Alveolaris.*
7. *SHUFFLEBOTHAM. *The Milroy Lectures on the Hygienic Aspect of the Coal-mining Industry in the United Kingdom. Lecture V. Beat Hand, Knee, Elbow and Buttock.*

2. The writers discuss the symptoms and diagnosis of puerperal infection with B. coli, and the prognosis and treatment of this condition. They are strong advocates of vaccine treatment, the details of which, with illustrative cases, they describe.

7. In the fifth Milroy Lecture, the writer describes "beat hand, knee, elbow and buttock." "Beat hand" is an acute inflammation of the subcutaneous tissue of the palmar surface of the hand and fingers, without history of injury, infection taking place through a slight abrasion often quite unnoticed. The course depends on its treatment, neglected cases often leading to a general septic condition of the hand. On the average 700 to 800 cases are reported each year. The treatment is that of any acute infection of a mild nature. Beat elbow, knee and buttock are similar conditions. He continues to discuss tenosynovitis of the wrist, and miners' itch or rash. This last consists of an erythematous or pustular eruption over areas chiefly exposed to coal dust and other sources of irritation. It occurs in certain pits or seams far more frequently than in others. In concluding his lecture, Shufflebotham discusses the Workmen's Compensation Act and further legislation needed to protect the miners' health. [J. B. H.]

1. In order to overcome the pronation which ordinarily results from both flaccid and spastic paralysis of the forearm, and thus to enable the patient to perform acts otherwise impossible, such as putting a fork or spoon into the mouth, Vulpius has devised two operations for fixing the bones in a position midway between pronation and supination. The first consists in turning a bone flap across from the radius and suturing it firmly to an area on the ulna which has been denuded of periosteum, following which procedure the arm is held fixed for ten weeks. The other method is to use a graft from the tibia, the principle of the operation being the same as in the first-mentioned. The author has been successful in both methods, and the patients have been able to do much more with the arm.

5. This is an unusual and interesting case,—a man of 40, in presumably perfect health, strong and rugged, was seized with violent cramps in the upper abdomen, with no temperature, no spasm or tenderness, no palpable tumor, no mass of any sort, and no vomiting till just before death, which occurred in collapse three days after the onset. Perforating ulcer and obstruction were ruled out, and though it seemed in some respects like tabes, the history was negative for lues. The whole case was very obscure. He was not operated on because the indications were not at any time clear, and when he began to go into collapse it was too late. Autopsy revealed gangrene of about one meter at the upper end of the jejunum, with fresh mesenteric thromboses in the radicles of the superior mesenteric vessels supplying this part of the gut, and an old chronic proliferative pylephlebitis. This condition has been reported several times before, and its etiology is obscure. In this case the mesenteric thrombosis was directly due to the process in the portal vein. [R. H. M.]

2. Schüller reports 4 cases of splenic tumor—2 of myelogenous leukemia, 1 of Banti's disease, and 1 of "aleukemic adenomatosis,"—treated by radium, mesothorium and rademanit, with distinct improvement in every case. The splenic tumor not only decreased in size, but the blood picture was more nearly normal and the general symptoms were alleviated. In the case of Banti's disease splenectomy was done following marked shrinkage of the spleen after the radium treatment. Besides claiming for radium the qualities above mentioned, the author states that it is active in cases where the Roentgen ray has failed; and that it causes so much decrease in the size of the spleen that it is a valuable measure to precede splenectomy. 4. Ruppert, L. *Cranial Heteroplastic Surgery with Celluloid; a Result of Twenty Years' Duration.*
5. Moczuiski, J. *Clinical Observations on the Inhalation of Tincture Strophanthus in Cardiac Insufficiency.*

2. The author states that the functional capacity of injured kidney tissue is usually very much underestimated and therefore leads to nephrectomy in cases where a conservative operation might restore the function of the organ. This is true especially in cases of intermittent hydronephrosis and pyelonephrosis, in which an operation establishing free drainage removes the pathological condition and restores normal function of the organ. The technic is difficult, but not impossible. He cites a number of operated cases with restored function, and no untoward secondary complications. Radical nephrectomy should be undertaken in his opinion only after an attempt and failure of the conservative, or in cases where the kidney parenchyma is so far destroyed as to make it useless. [F. S. K.]

4. Ettinger, W. *Three Cases of Malaria with Unusually Severe Symptoms.*
5. Fruhwald, V. *Two Cases of Perichondritis of the Thyroid Cartilage.*

2. The author explains the failure of atropin treatment in certain cases of dysmenorrhea by their etiology. He distinguishes two groups of dysmenorrhea, those that show definite vagotonic symptoms, in which the blood pressure is normal or nearly so; those that show no vagotonic symptoms, but rather circulatory disturbances, with an increase in blood pressure. In the first group atropin is of use; it fails in the second. These must be treated according to the underlying cause. [F. S. K.]

Obituary.

CHARLES PICKERING PUTNAM, M.D.

Dr. Charles Pickering Putnam, who died on April 23 last in his seventieth year, was born in Boston September 15, 1844. He was the son of Charles Gideon Putnam, M.D., and Elizabeth Cabot Jackson, both of Boston, and grandson of Dr. James Jackson. He graduated from Harvard College in 1865 and from the Harvard Medical School in 1869; continued his medical studies for a time in Germany, and began the practice of his profession in Boston in 1871. Since that time he had carried on a general practice, though for many years he made a specialty of pediatrics and did some excellent pioneer work in orthopedics. He was a lecturer at the Harvard Medical School on diseases of children from 1873-75 and a clinical instructor on that subject 1875-79. He served the Boston Dispensary as district physician from 1871-1873 and as orthopedic surgeon 1873-76. In 1898 he was elected president of the American Pediatric Society.

Dr. Putnam had been since the beginning of his practice of medicine a leader in charitable and social work,—almost from the beginning the most important leader of such work in Boston, the first to take hold and the last to let go of each new and important enterprise.

Dr. Putnam was one of the founders, in 1873, of the little-known but extremely important Boston Society for the Relief of Destitute Mothers and Infants, which was a pioneer in establishing the policy of keeping mother and child together, and was president of the society from 1904 until his death. In 1875 he became physician to the Massachusetts Infant Asylum, and from 1898 to 1910 he was also president of the board of trustees. The ordinary death-rate in such institutions was at that time something over ninety per cent. a year. The Massachusetts Infant Asylum had already brought the rate down to less than a quarter of that figure when Dr. Putnam became connected with it, and he by his skill and devotion again reduced it by two-thirds or more. He was one of those who in 1879 took part in the movement for establishing the Associated Charities, the second charity organization society in this country; and he was always one of the sustaining members of that society in the real, not the conventional, sense, working in many capacities, as president of a conference, as director, as chairman of many committees, including the present important one on inebriety, and, since 1907, as president.

From 1892 to 1897 Dr. Putnam took a leading part in the very important movement for the reorganization of the Boston Institutions for the care of prisoners, of the poor, and of poor, neglected, and delinquent children, being on the special committee appointed by Mayor Matthews in 1892, chairman of the board of visitors of 1893-94, chairman of the standing committee on pauper institutions of the advisory board appointed by Mayor Quincy in 1896, a steady fighter for the reorganization bill of 1897. When the new system of separate unpaid boards of trustees was established he was appointed a member of the Board of Children's Institutions, and was its chairman from 1902 to 1911, performing in that capacity a great and harassing, though invisible and unappreciated, service to his fellow-citizens.

Dr. Putnam was among the earliest supporters of Dr. James R. Chadwick in founding the Boston Medical Library, of which he was an original member in 1875, an incorporator in

1877, and which he served upon important committees until his death. He helped to organize and carry on the Directory of Nurses. He was active in the campaign against tuberculosis and a director of the Mental Hygiene Association. He was one of the first to take up broad social questions from the legislative end, was the first experienced charity worker to enlist in the Massachusetts Civic League, and helped secure the establishment of the State Board of Insanity, the taking over of the Boston Insane Hospital by the state, medical inspection in the public schools of Massachusetts, playgrounds, better probation service, the juvenile court, better laws dealing with tramps, with drunkards, and many others.

In short, Dr. Putnam was for a generation the backbone of social work in Boston. We have all looked to him to do the hard things—to take up the new line at which the timid balked and which the unimaginative could not see, sustaining the old from which the glamor had worn off, stiffening up the weak places, making the hard decisions. He was here, as in all things, a man to accept responsibility, take the burden on himself, and carry it,—a patient and successful physician to the community as well as to the child.

Dr. Putnam's most distinctive characteristic was the power of enlistment. In each of the many services he undertook it seemed to those he served and to his fellow workers as if that must be the only thing he had to do. There are in every enterprise the helpful men, the wise, the brilliant men, the steady workers. And then there are the essential men, those without whom the thing will not be done. In an extraordinary number of instances Dr. Putnam was among these last. Whatever happened, however badly things might go, whoever else became lukewarm or discouraged, his associates knew that he, at least, would see the thing through, that he had enlisted for the war, intended doing as much, be it more or less, as might be necessary. The time at his disposal seemed always to be infinite, and he had no observable bias as to hours. There is no evidence, known at least outside his immediate family, that he ever ate or slept, and three in the morning was apparently the same to him as three in the afternoon.

Dr. Putnam was a remarkably resourceful man and would reconstruct his patients' world, physically as well as morally, by his calm assumption that anything needed could be done, and in hundreds of cases by doing the most impossible parts himself. Slower minds thought him slow at laying the first brick, whereas he had completed the whole structure in imagination, and was hesitating what kind of chimney-pot to use.

Dr. Putnam had a fairy godmother quality, as many of us know. I remember on my first visit to his much-loved shanty in the Adirondacks I came to believe that if, when walking up a mountain, you happened to want anything, from a piece of maple sugar to a volume of Shakespeare or a box of paints, you had only to look under the nearest stump and you would find that Dr. Putnam had anticipated exactly that need at that particular spot.

To many of those who saw him, Dr. Putnam's impersonation of the policeman at the Charity Workers' ball a year or two ago (I personally took him for a real cop), and of the very "disturbed" patient who brought down the house upon the same occasion, was a revelation of an unsuspected quality. His sense of humor, indeed, lived always just beneath the surface. I once saw him "cure" a small child's hands by putting on them a couple of envelopes as mittens.

And the best was the power behind it all in the great kind heart, that would see and know only the best, and, with a quality like the sun, could see only light wherever it was turned.

MEMORIAL.

DR. CHARLES PICKERING PUTNAM.

THE committee on library and finance of the Boston Medical Library, at its regular meeting on Monday, April 27, desires in behalf of the Library to place on record an expression of its profound sense of the great loss the Library has sustained through the death of Dr. Charles Pickering Putnam, which took place after a brief illness on Wednesday, April 22.

Dr. Putnam was one of the five surviving charter members of the Library, and the only one who had served it continuously from the time of its incorporation in 1877. He was a member of the executive committee and of the committee on library and finance from the beginning of the Library. In 1879 a committee was appointed to provide for the registration of nurses at the Library. Dr. Putnam was one of the two constituting this committee and continued this service, latterly alone, with rare persistency and self sacrifice up to the present time. He had served on other committees at one period and another, and at the time of his death was the second member of the library committee, of which the librarian is the chairman. He was not only a member of committees but, notwithstanding his various occupations, was diligent in attendance and in the discharge of duties.

Dr. Putnam's service to the Medical Library from the point of view of continuity and devotion is peculiarly comparable with his service to the Associated Charities of Boston, which be helped to establish in 1879, to incorporate in 1881, of which he was vice-president from 1881 to 1907, and president from 1907 to the present.

Dr. Putnam's highly useful and unselfish activities were extended in many directions, in

all of which they were much appreciated and will be greatly missed.

Resolved, That this memorial expressing our sense of loss at the death of our colleague be spread upon the records of the Library and that copies be sent by the secretary to the family of Dr. Putnam and to the BOSTON MEDICAL AND SURGICAL JOURNAL.

Miscellany.

AMERICAN SOCIETY FOR CONTROL OF CANCER.

A PUBLIC meeting was held in St. Louis on Friday evening of last week, May 1, by the American Society for the Control of Cancer in conjunction with the St. Louis Medical Society.

"The general subject of the evening was 'The Prevention and Control of Cancer.' Hon. Charles Nagel, formerly Secretary of Commerce presided and his introductory remarks dealt with the importance of educating the public in regard to this disease. The first address was given by Frederick L. Hoffman, LL.D., statistician of the Prudential Insurance Company of America, whose subject was 'The Menace of Cancer.' He was followed by Dr. William F. Rodman of Philadelphia who discussed the prevention of cancer by the correction or removal of irritated parts, the control of cancer by early recognition and treatment, and the value of radium as compared with surgery.

"Dr. Leo Loeb, vice-president of the International Association for Cancer Research, explained the importance of cancer investigation and research, and Curtis E. Lakeman, executive secretary of the American Society for the Control of Cancer, described the purpose and plans of this national organization and the educational methods employed."

Similar educational meetings have already been held in New York, Chicago, Pittsburgh, and Portland, Me., and others are to be arranged for in Boston and New Orleans.

"The Cancer Society has recently made special efforts to enlist the coöperation of nurses and nurses' organizations in its work. It is believed that the instruction of nurses as to the essential facts in regard to cancer, particularly in women, will be of special value in leading to a more general dissemination of information in regard to the symptoms, diagnosis, treatment and prevention of this disease, and the great importance of early recognition and operation. A circular letter was sent to all nurses' training schools, clubs and settlements in New York City, asking that lectures to nurses on this subject be arranged. Favorable responses were received and recently the first of a series of meetings and lectures for nurses was held at the Henry Street Settlement, of which Miss Lillian D. Wald is head worker. About eighty nurses of the settlement staff were present. Another meeting will be held in May for the benefit of the several hundred visiting nurses of the New York City Department of Health.

"These facts have been submitted by the Cancer Society to the three national nursing organizations now meeting in joint convention at St. Louis, namely, The American Nurses' Association, The National League of Nursing Education, and the National Organization for Public Health Nursing, and the official coöperation of the nursing profession throughout the country is hoped for."

TRANSFER OF SURGEON-GENERAL'S LIBRARY.

AT a stated meeting of the committee on library and finance of the Boston Medical Library, held April 27, 1914, said committee having under its by-laws entire charge of the finances and of the management of the Library, it was,

Resolved, That the Boston Medical Library, a duly incorporated institution of Massachusetts, having a membership of 700 physicians in Greater Boston, funds amounting to over $500,000, and a library of 80,000 volumes and 56,000 pamphlets, having learned of the proposed amendment to the Army Appropriation bill that passed the Senate March 28, 1914, providing for the transfer of the library of the surgeon-general's office to and to become a part of the Library of Congress, wishes hereby to express its opposition to this amendment because the library of the surgeon-general's office comprising the largest collection of medical and surgical books in existence is, with its index catalogue, an inexhaustible mine of scientific information which through the liberal policy observed in the past, has been at the service of the entire medical profession of the United States. Merging the library with the Library of Congress could not fail to destroy its identity and to injure its usefulness to the medical profession of the country. The Boston Medical Library has in the past had frequent recourse to the national library to provide its research scholars with books not in our collection, and has looked to it as the repository from which comes all that is best in medical literature. Therefore, the Boston Medical Library is unalterably opposed to the proposed transfer, and hopes that the amendment will not become law.

The Appropriation bill is now in the hands of the conference committee of the Senate and House, and may appear in the House for action at any time.

It was therefore voted that copies of this resolution be sent to the following: Hon. Henry Cabot Lodge, Hon. John W. Weeks, Hon. Andrew J. Peters, Herbert Putnam, librarian of congress; Surgeon-General, U. S. A.; Dr. Fielding H. Garrison, assistant librarian; Hon. James Hay, chairman committee on military affairs, House of Representatives.

A letter received since the above was printed, from Hon. James Hay, chairman committee on military affairs, says that the Senate amendment to the Army Appropriation bill providing for the removal of the Surgeon-General's Library to the Library of Congress was defeated. This news is confirmed in a letter from Senator John W. Weeks, dated April 30, whereas Senator Lodge wrote April 29 that he had taken up the matter with the committee in charge, but without result. Therefore it would seem that the library's protest arrived in Washington at an opportune time.

ILLINOIS STATE CIVIL SERVICE COMMISSION.

NOTICE OF EXAMINATION.

Applications must be on file in Springfield before 5 p. m., May 13, 1914.

Examinations will be held Saturday, May 23, 1914, at each one of the State Charitable Institutions where applicants appear, for the following positions:

GRADUATE NURSE.—Class B, Grade I. Open to men and women between ages of 21 and 45 years. Salary $40 to $55 per month with full maintenance. In this grade are all positions in hospitals for the insane, the duties of which involve the care of patients under the supervision of the Chief Nurse and the medical staff, together with the direction of Attendants when necessary; requiring education equivalent to graduation from a nurses' training school in an Illinois State Hospital for the Insane. Scope and weights: training and experience, 3; technical knowledge of nursing, 7.

MALE SUPERVISING NURSE.—Class B, Grade II. (*Promotional only.*) Open to employes who have served six months in Class B, Grade I, prior to examination, are on leave of absence, or are eligible for reinstatement. Salary $50 to $70 per month with full maintenance. The duties, under the supervision of the Chief Nurse and medical staff, involve the general overseeing of the Nurse and Attendant force, caring for the patients in a portion of an institution; requiring at least six months' experience as a Graduate Nurse and some administrative ability. Scope and weights: special subject, including questions on administrative duties and practical nursing, 8; seniority, ½; efficiency, 1½.

Requests for information and application blanks should be addressed to W. R. Robinson, Chief Examiner, State Civil Service Commission, Springfield, Illinois.

NOTICES.

CONFERENCE ON THE STUDY OF EXCEPTIONAL CHILDREN IN OUR PUBLIC SCHOOLS.

Friday, May 1, 3 p. m., Assembly room (third floor), Psychopathic Hospital. "Methods of Studying the Exceptional Child," Dr. Yerkes and Dr. Puffer.

Friday, May 8, 3 p. m., Assembly room (third floor), Psychopathic Hospital. "A Study of Typical Cases," Dr. Puffer, Miss Hardwick, and Mr. Bridges.

BOSTON MEDICAL LIBRARY.

At the meeting of the Committee on Library and Finance of the Boston Medical Library April 27, the Directory for Nurses was placed in charge of the House Committee of the Library, the late Dr. C. P. Putnam having been a single sub-committee having the care of the directory.

Dr. Edward C. Streeter was appointed a member of the Committee on Library and Finance to fill the vacancy caused by the death of Dr. Putnam, and was assigned to the sub-committee on the Library.

SOCIETY NOTICES.

THE AMERICAN GYNECOLOGICAL SOCIETY.—The thirty-ninth annual meeting of the American Gynecological Society will be held in Boston Tuesday, Wednesday and Thursday, May 19, 20, 21, 1914. The scientific sessions of Tuesday and Thursday will be held at the Boston Medical Library and of Wednesday at the Country Club, Brookline. The headquarters of the Society will be at the Harvard Club, Boston.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—The sixty-fourth annual meeting will be held at the New American House, Hanover Street, Boston, on Tuesday, May 12, 1914. The business meeting will be at 5.30 p. m. and dinner will be served at 6.30. Tables seating eight will be used and members may arrange parties. Dinner tickets may be obtained from the secretary for $1.00 each. All members are urgently requested to pay their annual assessment of $5.00 at this meeting or forward it to the treasurer instead of making payments at The Massachusetts Medical Society meeting in June.

The Board of Censors will meet for the examination of candidates on Thursday, May 14, at 2 p. m., at Roxbury Masonic Temple, 171 Warren Street, Roxbury.

BRADFORD KENT, M.D., *Secretary.*

RESIGNATION.

Dr. Frederic M. Briggs has tendered his resignation as Professor of Surgery and Secretary of the Faculties of Tufts College Medical and Dental Schools, to take effect September 1, 1914.

RECENT DEATHS.

DR. HIRAM LUCE CHASE, who died on April 24 in Cambridge, Mass., was born at Boston in 1825. He received the degree of M.D. from the Harvard Medical School in 1846, and ever since that time had practised his profession in Cambridge. He was a member of the American Institute of Homeopathy and of the Massachusetts Homeopathic Medical Society. He is survived by one son, also a physician.

DR. WILLIAM J. O'REILLY, who died on April 24 in Roslindale, Mass., was born at Charlestown, Mass., in 1859. He studied medicine in New York and received the degree of M.D. in 1883 from Bellevue Hospital Medical School. He practised his profession for several years at Waltham, Mass., and then removed to Roslindale. He was a former member of The Massachusetts Medical Society.

DR. O. O. ROBERTS, who died on April 26, in Northampton, Mass., was born at Lyndon, Vt., in 1829. He received the degree of M.D. in 1853 from the Hahnemann College, Philadelphia. He settled at Northampton in 1857, and was the first president of the Western Massachusetts Homeopathic Medical Society.

DR. CHARLES EDWIN SANFORD, who died on April 26 at Bridgeport, Conn., was born in 1830. He received the degree of M.D. in 1853 from the Yale Medical School, and settled at Bridgeport in 1859.

DR. HARRY ATHERTON SMITH, who died on April 27, at West Roxbury, Mass., was born in Auburn, Me., on June 23, 1866. He graduated in 1886 from Colby College, and in 1890 received from the Bowdoin Medical School the degree of M.D. After serving as house physician at the Maine General Hospital, Portland, he practised his profession at Livermore, Me., for eight years, until he removed to West Roxbury in 1899. He was a former Fellow of The Massachusetts Medical Society.

Original Articles.

ON TERRITORIAL AUTONOMY IN CEREBRAL CIRCULATION AND ITS RÔLE IN THE GENESIS OF SYMPTOMS IN THE PSYCHONEUROSES.*

By J. W. Courtney, M.D., Boston.

In a paper on hysteria read before the American Neurological Association June 20th, 1884, Dr. Walton[1] makes the following statement; "Just what changes occur in the brain in hysteria, we do not know, and are not likely to decide for some time, but it will not be inappropriate, as bearing on the connection between hysteria and the ovaries, to present a few arguments here in favor of the vasomotor theory, by no means as underlying all hysteria or hysterical symptoms, but as best explaining that set, at least, of so-called hysterical cases in which hemianesthesia is the principal symptom.....

"It has been urged that the changes in cerebral activity, giving rise to these and all other hysterical symptoms, are dynamic, and not susceptible of explanation by so simple a physical phenomenon as contraction and relaxation of blood-vessels. To me, however, the explanation implicating the blood-vessels is by far the most satisfactory provided it meets all the requirements, and this it seems to do in at least the class of hysterical patients under consideration. ....;the sudden loss of function of the cortical cells of half the brain, as seen, for example, in hemianesthesia, may easily be imagined to supervene suddenly upon a more or less completed contraction of cortical blood vessels on that side from irritation of the sympathetic system in some part of the body. Loss of function would in this case persist as long as the contraction of vessels so continued, and at the same time the nerve cells would be ready to take up their duties instantly with the return of blood through cessation of the vascular spasm.....

"This theory by no means limits the cerebral disturbance to one side of the brain, nor on the other hand does it preclude a limitation of the vasomotor change to a small part of the cortex, as, for example, to that concerned in particular motions or sensations. At the same time it well explains the tendency of the symptoms to spread over an entire half of the brain and hence, of the body. To explain the predominance of sensory over motor symptoms, or the opposite, we have only to suppose the vascular spasm more complete over one than over another portion of the cortex."

In the discussion which followed the reading of the paper, the speakers, in the main, dissented from Dr. Walton's theory, but nobody brought forward the only insurmountable objection that could validly be raised to it, namely, that Dr. Walton's assumption of the existence of cerebral vasomotor nerves was entirely unsupported by any physiologic or anatomic researches up to that time made.

The history of the cerebral vasomotor nerves forms, to my mind, one of the most curious chapters in physiologic literature. As late as 1890. Sir Michael Foster,[2] in the third edition of his text book on physiology, says: "Moreover the flow of blood to, and consequent change in the bulk of the brain, as measured by the venous outflow, may be modified independently of changes in the general blood pressure. For instance, stimulation of the motor region of the cortex quickens the venous outflow, without producing any marked change in the general blood pressure; *this feature becomes very striking at the onset of epileptiform convulsions* when these make their appearance. It is difficult not to connect such a result of functional activity with some special vasomotor nervous arrangement comparable to that so obvious in the case of a secreting gland."

From 1890 to 1897 no noteworthy contribution to the literature of the nerves in question was made. In the latter year Hill and Bayliss,[3] after much elaborate and painstaking experimental work came forward with the following ultimata:—first, that no evidence was found by them of the existence of cerebral vasomotor nerves, either by means of stimulatoin of the vasomotor centre, or central end of the spinal cord after division of the cord in the upper dorsal region, or by stimulation of the stellate ganglia—in other words, by stimulation of the whole sympathetic supply to the carotid and vertebral arteries; second, that evidence is not forthcoming of the existence of any local vasomotor mechanism; and third, that the cerebral circulation in normal conditions passively follows the changes in the general arterial and venous pressures.

Curiously enough, in the self-same year, Obersteiner,[4] by means of the gold-and-sodium chloride stain, was able to demonstrate the presence of vasomotor nerves in even the finer cerebral vessels. Hill[5] had admitted the presence of undoubted muscular tissue in the vessels of the pia, but Obersteiner[6] went a step farther and, having pointed out the presence of a fully developed muscular media in all intracranial vessels, down to the finest subdivisions (Ubergangsgefässe) regarded this finding as sufficient evidence in and of itself of their innate power of independent contraction and dilatation. He laid great stress, however, on the ease with which the cerebral vasomotors became paretic and lost their power to respond at a time when those of other organs responded readily.

During the next year the published work of both Gulland[7] and Morison[8] abundantly confirmed Obersteiner's observation, and the existence of a special cerebral vasomotor apparatus

* Paper read before the Boston Society of Psychiatry and Neurology, Feb. 19, 1914.

seemed to be an established fact. There have been subsequent observations made in this same field although they are relatively few in number. In the main they substantiate the opinions of Obersteiner, Gulland and Morison. Four in particular are interesting by reason of the method employed. As you probably well know, it is now an almost universally accepted fact among physiologists that a positive reaction to adrenalin is a trustworthy proof of the existence and nature of the sympathetic nerves of an organ, and in the four instances just alluded to, the adrenalin test was made. Spina[9] found, after intravenous injection of adrenalin extract, that the cerebral vessels were markedly dilated; to such an extent, indeed, that, with an incised dura, a hyperemia sufficient in degree to cause a brain prolapse could ensue. By direct application of the same substance to the same cerebral vessels, Biedl and Reiner[10] found that these vessels could be brought into a state of contraction, but they also noted that when the pressure increase in the general circulation had become established, the brain anemia gave way before the general high blood-pressure.

Protopopoff[11] noted that either immediately or within a few seconds after the intravenous injection of adrenalin, a very marked arterial anemia followed and continued for from two to five minutes according to the dose employed. If the latter were large, the anemia was followed by a hyperemia of shorter duration. At times the effect produced was undulatory in character, that is to say, successive cycles of anemia and hyperemia to the number of three or four were observed. The venous circulation of the brain was either not affected at all or showed merely a slight stasis. It is Protopopoff's opinion that only the capillaries contract and that the calibre of the visible arteries is not changed. This contraction he looks upon as the result of the direct action of the adrenalin upon the vessel walls rather than of excitation of the bulbar vasomotor centre. To this same contraction rather than to increased cardiac energy he attributes the heightened blood-pressure. Adrenalin introduced into the stomach, he found to be absolutely inefficacious.

The last observation to be mentioned, that of Wiggers,[12] is the most noteworthy. Before making his experiment this author carefully considered all possible sources of technical inaccuracy, and ingeniously contrived to eliminate them. His experimental material was the decapitated head of a large dog. His conclusions are as follows:—

"1. By perfusing the isolated brain under constant temperature and pressure with a suitable solution and continuously recording the entire venous outflow, the effect of influences which alter the size of the brain vessels can be definitely ascertained.

"2. The application of adrenalin solution to such a preparation in such a way as not to introduce factors themselves conducive to outflow change, caused reactions which corresponded to those obtained from the vessels of other regions.

"3. These reactions, if induced through the stimulation of vasomotor nerve ends, as claimed by certain workers, supply physiological evidence of the existence of such nerves."

In spite of certain rather marked discrepancies in the results obtained by the observers quoted, it seems to the writer that the bulk of the evidence unquestionably establishes the existence in the brain of a "special vasomotor nervous arrangement comparable to that so obvious in the case of a secreting gland."

When we take into consideration the highly differentiated functional value of the various brain areas and the wide variations in degree within which certain of these areas, either singly or in groups, are from moment to moment called into activity, while others either adjacent or remote, are practically quiescent, it is impossible to believe that the cerebral circulation passively follows the changes in the general arterial and venous pressures. Not only in the secreting glands but elsewhere throughout the economy, Nature has provided for local activity and local rest—in other words, for local waste and repair —in the form of circulatory autonomy. And it is entirely incredible that having thus endowed the vegetative organs, for example, she should freakishly have turned her back upon the brain.

In 1899, in a paper[13] on traumatic cerebral edema, I exploited what I believed to be the rôle played by the cerebral vasomotors in the production of this pathologic condition. At that time I was quite unaware that Dr. Walton had advanced the theory that these same nerves were the medium through which hysteric symptoms came into being. I was equally ignorant of the existence of his theory when the present paper —the outcome of long and careful independent consideration of the subject under discussion— was begun. It gives me, therefore, the greatest pleasure to announce at this time that, so far as the views about to be set forth relate to the pathology of hysteria, they are, in essence, identical with those published by Dr. Walton in 1884.

Directly we establish the existence of the power of independent dilation and contraction on the part of the vessels of the brain, we may logically assume that that organ, in common with other parts of the economy provided with an identical autonomic circulatory apparatus, receives, under normal circumstances, a supply of blood nicely proportioned in quantity to the functional activity of the moment. And when we consider that this activity is a constantly changing one with regard to both area and intensity, I think we may carry our assumption farther and safely postulate the existence of a territorial autonomy in cerebral circulation.

Physiologically, we have presumptive evidence of it on every hand. For example, when the muscular system is practically in a condition of absolute rest and the mind is intensely absorbed

in study, it is unbelievable that the Rolandic area and those which govern certain of the special senses, notably hearing and smell, are each receiving at the same time an amount of blood equivalent to that circulating through the prefrontal region of the cortex. It is equally unbelievable that in the cortex of a person walking along with hands in pockets, deeply engaged in pondering some perplexing problem, an equal volume of blood is passing through the prefrontal lobes and those which preside over the inert upper extremities and the automatically acting lower respectively. If it were necessary, examples of this sort could be multiplied almost indefinitely.

Pathologically, we have two forms of presumptive evidence of the existence of cerebral territorial circulatory autonomy—direct and indirect. The first is clearly manifest when the cranium is opened and certain portions of the cortex observed in cases where the brain has been contused by a diffused traumatizing force. Here one not infrequently finds in the absence of all discoverable pressure from within or without, cortical areas that are absolutely pulseless side by side with others which are pulsating normally. This fact, striking as it is, is easily paralleled in significance by the experience of surgeons who are constantly discovering, even in exploratory operations upon non-traumatized brains, that anything beyond the most gentle manipulation of the cortex is followed by cessation of pulsation in the regions palpated.

Indirect evidence on the point in question is derived from observations in regions other than the brain whose vessels are supplied by the autonomic system. Here, for the sake of brevity, will be mentioned only the striking and common examples of morbid local autonomic function, namely, isolated congestion of the ears, spontaneous ecchymoses upon the surface of the extremities, spontaneous edema and the various forms of akroasphyxiation. The last-named term is to be taken in its broadest sense and is meant to include manifestations ranging in severity from the more or less permanently cold and mottled extremities and the so-called dead fingers of the neurotic to the gangrene of the victim of Raynoud's disease.

The evidence thus far adduced may fail to bring about a universal admission of the existence of an autonomic, particularly of a territorially autonomic cerebral circulatory system. But it seems to me only fair to maintain that the facts brought forward in the hope of inducing belief in its existence are, to say the least, quite as material as those which underlie many of the generally accepted beliefs of neurologic and psychiatric science. And when it comes to a concrete conception of the pathologic substratum of the clinical phenomena observed in those nervous states broadly termed neuroses and psychoneuroses, it seems to me infinitely more scientific and more in harmony with the terms of pathology to designate it as a cerebral vasomotor ataxia, than to evade the issue with purely psychologic abstractions. When one speaks, for example, of hysteria as a dissociation of the personality, a limitation of the field of consciousness or a conflict in the unconscious it is tantamount to a begging of the question—to an attempt at explaining a pathologic process by a single symptom chosen arbitrarily from the great symptomatic complex to which the process gives rise.

The direct and absolute relationship of vasomotor activity to the normal functioning of a part has never been more strikingly shown than in the experimental work of Cannon[14] upon the alimentary canal of animals. This observer found that not only were the secretory activities of the stomach affected by the stronger emotions but that the movements of the stomach and, indeed, of almost the entire alimentary tract as well, were wholly stopped during excitement. If we had no other facts upon which to base an analogy it seems to me that Cannon's findings, in and of themselves, warrant the assumption that the disordered brain function underlying hysteria, is directly traceable to changes in vascular tension.

The mode of onset, the distribution and the general behavior of hysterical symptoms all accord with such a view. In the emotionally induced crises we see very clear evidence of the varying degrees with which different brain areas respond to the change in vascularity. Beginning with the small facial muscles the motor excitement affects progressively more numerous muscles and larger muscles and finally ends in sardonic laughter and violent contortions. When the motor storm is over we discover the havoc wrought in the vasomotors of certain brain areas by the pathologic stimulation of the emotion. This is usually in the form of anesthesia distributed in disseminated islets or involving an entire half of the body; of mono- or hemi-plegia, a contracture of a limb or an abolition of function of one of the sense organs. Nothing could more clearly indicate a territorial vasomotor paresis than this.

The same paresis is manifest when one or more of the above phenomena appear, as is sometimes the case, without any preceding emotional storm, and it is here that the notion of territorial circulatory autonomy gets its strongest support.

Phenomena in the intellectual sphere, such as changes in the personality, are explainable, I believe, on precisely the same ground. In recorded cases where hysterics have, through successive retrograde changes, dropped from the intellectual level of adult life to that of infancy, the extent of degradation noted in the successive changes is probably directly proportionate to variations in local vascular tension. If we seek for analogous phenomena elsewhere in brain pathology, we find them in the retrograde mental changes accompanying the cerebral anemia of atheroma and syphilis. In the two latter dis-

eases, to be sure, the anemia which produces intellectual retrogradation leads also to cellular decay. And it may properly be objected that no such cellular decay is found in hysteria. In the great majority of cases cellular decay is of course absent, because the extreme variations in the tension of the brain arteries in hysteria are almost never of sufficient duration to permit of such a pathologic process. That this is not universally the case, however, I hope to show in a subsequent paper where I shall report the complete microscopic findings in the brain of a case of hysteria of unquestionable genuineness.

Cellular degeneration does not take place in those brain areas whose perturbation of function is manifest by the so-called permanent stigmata, which, incidentally, are always sensory or sensorial in character; or by such apparently more or less persistent phenomena as hemiplegia, monoplegia and contracture, because these phenomena are in reality intermittent and do not persist during sleep.

It might pertinently be asked upon what grounds the rather wide variations in cerebral vascular tension, which are assumed to regulate the variations in the severity of the hysterical phenomena, are based. In reality, it is based in part upon the experimental work, particularly that of Protopopoff, quoted above, and in part upon analogy, since precisely the same variations are manifest in the akroasphyxiations where widely varying degrees of intensity of vascular spasm are betrayed, as has been said, by coldness and mottling of the skin, by the so-called dead fingers, by akrocyanosis and by actual gangrene. Analogous variations may also be found in the case of the stomach and bladder during states of emotional excitement.

Edema of brain tissue consequent upon vasomotor ataxia probably rarely ensues on account of the transitory character of the ataxia and the really moderate degree to which the ataxia is probably in most cases limited. In the rare cases in which it might occur it would naturally be limited in distribution and readily carried off through the sinuses.

The physiologic and pathologic principles above set forth seem to the writer to apply with equal force to the interpretation of the clinical manifestations of epilepsy and migraine.

In the former disease the territorial defects in arterial functioning are clearly manifest in spasms confined to limited groups of muscles and to sudden changes in the personality. The more diffused effects of vasomotor ataxia are probably responsible for the grand mal attacks. The difference between epilepsy and hysteria, pathologically speaking, lies in the degree of activity rather than in the nature of the provocative agent.

The same statement is also undoubtedly applicable to the relationship between the above two diseases and migraine. In the last named the vascular spasm is peculiarly territorial, as ophthalmoscopic examination made during the attack would seem to indicate. Parisotti,[15] for example, had the opportunity of making such an examination and found that, with the loss of the lower field of vision, there was marked narrowing of the arteries of the upper half of the retina, with normal calibre of those of the lower half. Subsequent to the attack the spasm had disappeared.

Quaglino[16] found narrowing of the calibre of the retinal arteries during attacks of scintillating scotoma lasting from five to fifteen minutes, during which there was transitory loss of vision, with bright elliptic figures bounded above by a radiating halo.

Seagrist[17] observed marked narrowing of the retinal arteries on the side of the hemicrania during the attack and was able to corroborate the observations during a second attack.

To those who welcome the abstruse, the nebulous and esoteric in theories concerning the pathology of the psychoneuroses, so simple a conception as that of a territorial vasomotor ataxia will make no appeal. There are, however, certain strong points in its favor which cannot be gainsaid. These have already been hinted at or specifically mentioned, but will, I think, bear recapitulation here: first, it is universally intelligible; second, it does not attempt to explain a pathologic process by a single clinical symptom, to which the process gives rise; and third, it harmonizes with the general concepts of pathology.

DEATHS FROM SNAKE-BITE IN INDIA.—In the year 1908, 19,738 persons died of snake-bite in India; in 1909, 21,364; in 1910, 22,478. The number of persons killed by tigers in 1908 was 909; in 1909, 896; and in 1910, 853.

TEN TESTS BY WHICH THE PHYSICIAN MAY DETERMINE WHEN A PATIENT IS CURED OF GONORRHEA. A STUDY OF 1260 TESTS BY CULTURE AND SLIDE OF THE EXPRESSED PROSTATIC AND VESICULAR SECRETIONS.*

BY CHARLES M. WHITNEY, M.D., BOSTON,

Professor of Genito-Urinary Diseases, Tufts College Medical School; Surgeon to the Genito-Urinary Department, Mt. Sinai Hospital.

THAT gonorrhea is a most serious and dangerous disease, is admitted by every physician who has observed its disastrous effects. It is responsible for one-fourth of all the blindness in the world, for thousands of deaths from secondary kidney disease following stricture, for many fatal cases of gonorrheal salpingitis and secondary peritonitis, and for metastatic gonorrhea (the so-called gonorrheal rheumatism) which results in temporary or permanent loss of function in one or many joints.

It is stated by specialists in that line that gonorrhea is the cause of 60-80% of all gynecological operations. We should add to our list of disasters sterility in both men and women.

From this brief review of the subject it is clear that all preventive measures which tend to lessen the spread of this disease should receive the thoughtful attention of every physician.

This paper will not discuss the ordinary clinical symptoms and treatment of this ailment, for it is wholly concerned in answering these very important questions, when is gonorrhea cured? How may we assure a patient who has had it that he may marry without danger of infecting his wife? It would seem at first sight that the answer was easy, that when the discharge stopped, and the urine was clear, and there was no return of the symptoms, that the case was well. This is usually the patients' view and because of this many serious and unfortunate results are observed. In spite of a clear urine and no discharge for months, gonorrhea may exist in an active and dangerous form. The explanation of this is found in the peculiar and complex structure of the urogenital organs. The urethra, in which the infection first occurs, is divided into the anterior and posterior portions by the compressor urethrae muscle. In the anterior portion there are along the urethra, the lacuna magna, and the follicles of Littrè and Morgagni, in all of which the gonococci may be concealed and give no symptoms.

In the bulbous urethra upon the floor are the two openings of Cowper's glands, the ducts of which are nearly two inches in length and end in small glands which are situated between the layers of the triangular ligament. Along this duct the infection may extend, giving rise to no symptoms until some cause starts it into activity, when it may infect the urethra and cause a profuse discharge. When we pass the compressor urethrae muscle we enter a portion of the urethra, which has many and important structures leading from it.

In the median line is the veru montanum, with the colliculus at its apex, on the walls of which the ejaculatory ducts are to be found. Along the floor are the prostatic sinuses, from which many glands lead into the prostate.

Connected by the ejaculatory ducts are the seminal vesicles, composed of tubules and blind cul-de-sacs.

It is possible for the gonococcus to enter these ducts and organs and remain latent many months or years. If the disease did not extend beyond the compressor urethrae muscle the danger of latency would not be as great, for probably 90% of relapsing cases are due to the prostate and vesicles, but the unfortunate fact is that from 60% to 80% of cases do progress beyond this muscle and become posterior, either with or without subjective symptoms. Hence it is obvious that before deciding upon a cure these organs should be carefully examined to determine that no organisms are present.

Assuming then, that a patient presents himself for examination as to whether he is cured and in proper condition to be married or to resume marital relation if already married, what steps should we take to assure him that the disease is no longer present?

Two classes of cases are seen: first, those in which the disease has been a first infection and has been acute and uncomplicated, and second, the chronic and protracted cases which have resisted treatment, are usually not primary infections and have resulted in some organic change in the anatomic structures.

In the first class there is less danger of latency than in the seconad.

1. *Discharge.* Regardless of which class the case belongs to, we should begin our examination by an inspection of the patient's urethra to find out whether any discharge is visible at the meatus and if not, the urethra should be gently stripped.

If present it should be looked at with suspicion and carefully examined for gonococci. If it contains only mucus, epithelium and an occasional pus cell it may be harmless, but a culture of it should be made to prevent any possibility of error. If no discharge is present inquiry should be made as to how long a time has elapsed since urination, and the patient should be told to carefully examine the meatus in the morning before urination and if discharge is present it should be placed on a slide for examination.

2. *Urine.* If no discharge is found we should now examine the urine as to its clearness and freedom from shreds. A turbid urine which

* Read before the Somerville Medical Society, March 4, 1914.

does not clear upon the addition of acetic acid, shows a chronic inflammation, and the examination need proceed no further for it is obvious that the disease is still present. If clear and shreds are present, their size and action in the urine should be noted. If they are large and sink quickly they contain a large amount of pus and indicate an inflammatory area somewhere along the urinary tract which must be located and treated. If small, or light and flocculent, they are chiefly mucus and epithelium and are not usually of diagnostic value, merely indicating a mild urethral catarrh.

Not a great deal of information is gained from the microscopical examination of these large shreds. Some years ago the writer investigated them by preparing over a hundred slides and several hundred fields were gone over with the result that gonococci were found in only two large shreds.

Therefore other means will tell us more quickly and accurately whether the disease is present.

3. *Instrumental Examination of the Urethra.* By the bougie-a-boule we should examine the urethra for stricture and for tender areas. If the meatus is small it should be divided to permit the passage of instruments.

If a 28 or 30 bougie-a-boule passes freely to the bulb and shows no stricture or tender spot, and if a 28 sound passes to the bladder easily and without causing bleeding we may feel fairly well assured that no stricture exists in the urethra which might cause a relapsing discharge.

4. *Urethroscopic Examination.* By this we can ascertain the condition of the urethral mucous membrane and can occasionally see the minute openings of inflamed follicles.

If localized congestions or erosions are present they should be placed under treatment by local application of silver nitrate, which will provoke a discharge which should be examined.

5. *Examination of the Prostate and Vesicles.*—With the bladder partially filled with urine or boracic acid solution, the prostate and vesicles should be examined and their size, consisteney and sensitiveness should be noted. If boggy, enlarged or tender, it indicates the need of treatment, at any rate, and the possibility of latent disease in these organs.

Whatever the condition found may be, gentle massage should be done and the vesicles stripped. The discharge appearing at the meatus should be saved on a slide, or Petri glass, and examined later.

The urine or solution should now be passed and if many "snowflake" masses are present they should be examined microscopically. They almost surely mean vesiculitis, and a patient having this cannot be called cured.

The very important and vital examinations of this expressed secretion by culture and slide will be later referred to at length.

6. *Test by Alcohol.* If the patient has successfully passed the foregoing tests he should now be permitted to take malt liquors (the so-called "beer test") or spirits.

The results should be carefully noted and also the character of any discharge produced by them.

7. *Coitus.* This test cannot properly be included among those which should be used, because no physician would permit a patient to risk infecting anyone else. Nevertheless, there are patients who have no sense of moral responsibility and from their errors certain conclusions can be formed, provided a protective covering is used. In case the discharge returns we know it was a relapse and not a new infection.

8. *Discharge Induced by Irritating Antiseptics.* This so-called provocative method consists in irrigating the urethra with some irritating chemical substance producing a urethritis, and the resulting discharge may show gonococci in the pus cells which have come from the deeper layers of the urethra. Nitrate of silver is the best antiseptic for this purpose and should be used as an anterior injection in the strength of 1-4000 and also as a deep urethral irrigation in the strength of 1% in a Keyes-Ultzmann syringe.

I am in the habit of passing a full sized sound before using the injections to dilate the urethra and to express from the follicles any retained contents.

9. *Bacteriological Examination of the Expressed Vesicular and Prostatic Secretion by Culture and Slide.* It is very interesting to note that in 1878, one year prior to the discovery of the specific organism of gonorrhea, the attention of the medical profession was called to the possibilities of its latency by Emil Noeggerath of New York. At that time his conclusions were ridiculed but today it is generally admitted that this disease may remain latent for months or years. The discovery of the gonococcus by Neisser in 1879 and its growth in a culture medium by Bumm in 1887 were the beginnings of better days, for it is no longer necessary to grope blindly in the darkness of ignorance for the causative factor of the disease, but its presence or absence may be seen in the clear daylight of scientific accuracy. The work so ably started by these pioneers has been the means of helping us to recognize many obscure conditions due to this organism. The difficulty of determining whether or not a patient is the host of the gonococcus has not been lessened since the publication of my first paper in 1911 (Chronic Relapsing Gonorrhea and the Methods Used to Determine Its Cure), and the larger series of cases which are now reported have emphasized the facts then stated.

These cases, which have been studied by my colleague, Dr. A. C. Pearce, and myself, have made us realize more than ever the responsibility placed upon the physician who is called upon

to determine whether or not a man may safely marry.

In order to answer this question intelligently it is absolutely necessary that the patient should be under observation a sufficient length of time to allow various tests to be made, which require at least three weeks. We have been repeatedly called upon to determine whether or not a man is cured of his ailment and been told by him that he has made all arrangements for marriage in a week or ten days. He would certainly be placed in a very unpleasant position in case our examination showed the presence of gonococci. The insidious character of latent gonorrhea has repeatedly manifested itself in our series of cases. Time and again a patient has been examined who has a clear urine, no visible discharge at any time, with few if any shreds, and upon stripping the seminal vesicles we have found them loaded with pus. Whether or not we find the gonococcus in the expressed secretion we consider this man a menace to the community and he should not be allowed to marry until we have improved his condition. The presence or absence of chronic seminal vesiculitis cannot always be made by rectal palpation alone. It can only be made in some cases by a physical and microscopical examination of the expressed vesicular secretion, because the vesicles are not always enlarged to touch.

Manifestly, then, such an examination is indispensable in ascertaining the presence of a latent form of gonorrhea. In considering the prostate as a harboring place for these organisms we believe that too much importance has been given to it. We know that the disease does infect the glands leading from the sinuses, the colliculus, and may enter the tissues of the gland itself, but these are reached by treatment through the urethra, while the seminal vesicles, with their honey-comb structure so ideal as culture media for organisms, can only be indirectly treated by stripping and in intractable cases by incision or excision of these organs. This means a severe and mutilating surgical operation, which may be dangerous to life. While this is rarely necessary, there are cases which will yield to no other means. The fact that so few patients who have a low grade chronic prostatitis are sterile would lead us to believe that its secretory action is not markedly disturbed, but it may still excite the motility of the spermatozoa and may also stimulate the testes in the formation of them. In the examination of a patient to determine the presence or absence of gonorrhea our methods are substantially the same as reported in our first paper.

The patient is instructed to report with a full bladder. Any secretion appearing at the meatus is obtained on a slide and reserved for future examination. The anterior urethra is cleansed with normal salt solution, which will not affect the growth of the gonococcus, and the glans penis is cleansed with alcohol, which causes a temporary burning sensation if it enters the meatus or comes in contact with the scrotum. The patient then assumes a crouching position with the knees slightly bent and the back parallel with the floor. The vesicles are then vigorously massaged and the strippings allowed to drop into a tube containing the culture medium. A series of slides is made and then the patient passes his urine into a clear glass. This is later centrifuged and examined for pus and cocci.

The culture tube is incubated for 24 to 48 hours. The slide gently fixed with heat and placed in a solution of equal parts of ether and alcohol, to be stained later by the Gram method. The examination of the unstained slide is done immediately and the addition of a weak solution of acetic acid aids in detecting the pus corpuscles.

The culture media described in my previous paper have been found fairly satisfactory and we have chiefly used the nutrient blood agar in the proportion of one part blood to two parts nutrient agar. The latter is prepared by extracting one pound lean beef by immersion in 500 c.c. cold water for twenty-four hours, and then bringing it to a boil and skimming the surface. Then we add 40 grams of agar, 10 grams sodium chloride and 1 litre of water. Titrate 8-10 of one per cent. to phenolpthalein. The growth of gonococcus outside of the body in even the most carefully prepared media is uncertain because of its low vitality. One or two degrees of temperature above or below 38° Centigrade is sufficient to make the test valueless. It is therefore necessary to have the patient examined near to the thermostat in which the culture tube is to be placed because it cannot be transported from a distance in the varying temperatures which occur in this climate.

Another difficulty is the frequent and rapid growth of other organisms than the gonococci, for it is rare to get a pure uncontaminated culture.

The series here presented consists of 1260 examinations by culture and slide.

To properly understand the importance of the results obtained it is essential to state that nearly all these cases had been treated thoroughly by all modern means before they were subjected to these tests. In acute cases the vesicles were massaged after apparent recovery and the urethra examined, and in the chronic ones where the disease when first seen had existed from six months to eight years they had been treated for months by urethral dilatation and local urethroscopic applications, as well as by thorough and repeated prostatic massage and vesicular stripping, with the usual antiseptic irrigations and instillations. Further, the majority of these cases were private patients of the writer, others were sent by their physician for these tests, and a very small proportion were from the clinic, where they had been subjected to thorough and careful treatment.

Let us see what the examination of these

well watched, carefully treated and apparently cured patients showed. Gonococci were found as follows: By slide alone, 63, or 5%; by culture and slide, 44 positive, or 3½%; by culture alone, 26 positive, or 2%. In other words, from two to five men in every hundred who were clinically well harbored active and dangerous gonococci. It is sad to think of what the effect of marriage upon innocent wives and future children would have been. No patient who has had gonorrhea even in the distant past should neglect the precaution of these careful examinations to protect his health and that of those who will be near and dear to him in future. None of these cases had less than three examinations and we should insist on that number of cultural examinations at least, and more if the slide contains much pus. Some of our positive results were obtained on the first examination, while in others they did not appear till the second or third one.

It is needless to say that every one showing positive results was again subjected to treatment which was continued until we obtained three negative results, and up to the present not one of these men who have been married have had any return of their discharge nor have their wives been infected.

Many interesting results have been obtained from the bacteriological study of these cases as to the other pathogenic organisms which follow the gonococcus and serve to keep up a urethral discharge in some cases, but the limits of this paper do not permit a description of them. With new culture media the more accurate will be our results and the greater our assurance that physicians may do a beneficent work in the community by educating their patients to have these tests made.

10. *The Complement-Fixation Test.* This new and apparently valuable addition to our methods of determining the presence of gonococci or their toxins was first brought into notice by Schwarz and McNeil in an article published in the *Journal of the Medical Sciences* for May, 1911. Prior to that work along this line had been done by Mueller and Oppenheim, but it was not sufficiently conclusive to attract the attention of the scientific world.

This is similar to the Wassermann test for syphilis and follows essentially the same technic. It has been found necessary to use a polyvalent antigen, that is, one made from several strains (usually twelve) of gonococci. By this we determine the presence in the blood of an antibody produced by the gonorrheal organisms in the blood current or in the tissues of some organ, like the prostate, vesicles, or the joints. In an acute case it is not found before four weeks, and apparently remains long after the disease has clinically disappeared. It has been found after all microscopical and cultural tests have proved negative. These facts are most startling and point to the possibility that gonorrhea is not so local a disease as we have supposed it to be.

Not enough evidence has yet been produced for us to say that a positive result shows the presence of living gonococci somewhere in the tissues of the body, nor have we any way of knowing how long the antibodies may persist after cure. This is a most important fact to find out as otherwise we cannot wisely advise those patients whose test has proved positive. The test is exceedingly delicate and can only be done in a well equipped laboratory, and even there strange variations in the results are obtained. A clinically clear case of gonorrhea may show negative results, while one which is well by other and better tests may show positive results. The time has not yet arrived when we can depend upon this test alone and we must therefore place our faith in the tests which are of proven value and which will assure safety to our patients.

These tests which have been described are those which the physician should recommend to his patient, and by so doing he may lessen the peril of latent gonorrhea. He will do more than that for he will awaken in the public mind a realization of the fact that an apparently cured patient is not surely well, but that the consequences of his folly and misfortune may follow him all his life unless he receives competent and skillful treatment from his physician until he is cured, clinically and bacteriologically.

With the treatment of gonorrhea thus placed upon a plane as high as other diseases of far less importance we will hear less silly talk of the physician prolonging a case for financial reasons, we shall see fewer and fewer patients applying to druggists for nostrums promising a quick cure, and we will soon find that men having gonorrhea will aid their physician in their conscientious efforts to rid them of this dangerous malady.

SOME HYGIENIC TESTS APPLIED TO ORTHOPEDIC CONDITIONS.

BY H. W. MARSHALL, M.D., BOSTON,
AND
H. L. LANGNECKER, M.D., BOSTON.

IT IS rather interesting in view of the great dependence placed upon personal hygienic measures in treatment of so many diseases, that so few precise hygienic methods have come into general use, ones that can be employed in recording conditions and changes in normal healthy functions from time to time with exact quantitative degrees of accuracy.

If a mechanic attempts to regulate a complicated piece of machinery, he must know all normal actions of the machine, and the degrees that these actions are influenced by different defects which happen to exist in each instance; and if he does not possess means of measuring

such normal conditions, nor the changes in them in response to his manipulations, probabilities then are strongly in favor of bungling readjustments. And the question has been asked properly why the same probabilities for poor results do not exist when varying degrees of normal human functions are inadequately recognized, and when therapeutic procedures are crudely estimated, or are wholly unmeasured in the treatment of human maladjustments.

The writers have attempted to approach the problem of more accurate hygienic regulations for joint troubles in the following way: The individual heart has a certain functional capacity that depends upon its size, the strength of its muscular walls, the integrity of its valves, and upon other considerations. And by measuring the degrees and variations of blood pressure some quantitative idea can be obtained of the organ's efficiency as it is functionating normally under the special conditions which exist within it. Blood pressures accordingly may be used as rough indicators of normal cardiac functions.

In the lungs the total air capacity may be taken similarly as an approximate gauge of normal pulmonary function regardless of pleural adhesions, diseased areas in the lungs, and so on.

Volumes and specific gravities of urines suggest quantitative amounts of normal work that kidneys are doing at the times the quantities and specific gravities are measured, irrespective of whether casts, albumin, or other evidences of renal disease exist.

Varying degrees of muscular strength are measures of the varying normal functional activity of muscular tissue; and amounts of food, eaten as dictated by the natural appetite, can be taken as very rough quantitative indicators of normal digestive functions if twenty-four-hour quantities of food are weighed before being consumed.

The percentage of haemoglobin in the blood furnishes an idea of the efficiency of the blood with respect to its normal oxygen carrying functions; and also it is possible to judge whether a nervous system is very vigorous or very weak by the hours of sleep taken, when allowances are made for unusual amounts of exercise, worry, *et cetera*.

An individual's weight is a measure of the fluctuating balances which have existed in the past between activities of different organs; while weight fluctuations, from time to time, measure changes continually taking place in the complex physiologic balances among the related organs of every individual.

If all normal functions of all important organs could be measured simply and accurately by clinical methods, we should, have a precise way of stating personal idiosyncrasies and peculiarities that now are designated under vague terms of plethoric tendencies gouty diatheses, nervous temperaments, debilitated and auto-intoxicated states, and others. We would then have definite formulae showing ratios between normal activities of different organs in each individual, as well as absolute degrees of physiologic activity of each organ.

But if one examines a physician's report one usually finds particular emphasis laid upon existing abnormalities and defects without any stated estimation of their probable influence upon healthy relations and functions; although there may be perhaps some vague observations that the individual's general condition seems to be "fairly good" or "rather poor." A lung may be tubercular, however, or a heart may have leaky valves, or a kidney show evidences of nephritis, or a digestive tract exhibit various peculiarities, and the person as a whole may still be active and able to perform his ordinary daily work for a considerable period of time. It should be recognized that these abnormalities are of moment only as they influence present or future normal physiological functions; and the writers wish to emphasize this fact, yet at the same time it is not intended to minimize the other side of the situation, namely, the great importance of knowledge of pathological anatomical peculiarities.

Medical literature of the past shows scanty hygienic data applied to orthopedic cases. Practically none of the older records can be considered complete or adequate in showing quantitative variations which occur from time to time. An attempt has been made therefore in this paper to tabulate in more available form some of the more easily measured normal functions and conditions, arranging them in a way that they can be understood at a glance, and showing variable proportions among different combinations, as well as absolute degrees each measurement exhibits. The relation of each observed condition to the average figures for the same condition among collected large series also is roughly indicated.

Data has been obtained from various sources. From tables of physical measurements made in gymnasia it was found that five feet seven inches and one hundred pounds can be taken as fairly representative figures, respectively, for average heights and weights. Eight hours is commonly considered a fair average for the number of hours of sleep required. Text books have yielded other approximate normal averages as follows:

Average vital lung capacity for an adult, 3700 cc., W. H. Howell, Text-book of Physiology. Average brachial blood pressure in adults (systolic), 110 mm. of mercury, Joseph Erlanger, quoted by W. H. Howell, text-book of Physiology. Average specific gravity of urine, 1.017-1.020. Olaf Hammarsten, text-book of Physiological Chemistry. Average volume of urine in patients treated in United States—1200 cc. for males and 1000 cc. females—C. E. Simon, Manual of Clinical Diagnosis.

Average amount of animal food—10 oz. Av-

erage amount of water—50-60 oz. Average amount of vegetable food—30-40 oz.—W. Gilman Thompson, Practical Dietetics. Other average amounts have been assumed less accurately for exercise, muscular strength, nervous reflexes, *et cetera*.

All these have been set down arbitrarily in a table at points marked off upon a straight line. Variations from these averages have been indicated in a convenient way upon perpendicular lines drawn through the straight line of averages, one for each average figure. Each perpendicular has been divided then into a scale to show degrees of variation possible for each separate condition.

Having selected this method of recording results, patients have been weighed, measured, tested with spirometers, blood pressure apparatus, dynamometers, etc.; and from results obtained a curve has been plotted for each individual. Using the table as the pattern for all records, sheets of thin paper have been placed over the table and straight lines drawn upon the blank sheets to coincide exactly with the straight line of averages of the table. Then various numbers obtained from each patient are marked off upon the individual sheets by looking through them to the right places upon the proper perpendiculars of the table. Points thus located then have been joined together into a continuous irregular line as is indicated in the diagrams below.

These irregular curves show easily the variable combinations, the deviations of each variable from the average, and the changes that occur from time to time.

There are many limitations to this graphic method, but before these are discussed a few cases will be cited to illustrate the advantages.

The first chart is that of a woman of thirty years. She was delicate as a girl, and appears now thin, flat-chested, and with poor muscular development. She is engaged at an indoor occupation, sits at her task of proof-reading, and gets outdoor exercise mainly from walking to and from her work.

Several physical examinations in the past have revealed no serious pathological lesions of her organs, and she has been cared for by a number of competent physicians. Fearing that she might become helplessly crippled she sought further advice, and came for treatment before she was seriously incapacitated.

She represents an under-developed woman who has been pushing herself to the limit of her vitality constantly in her daily pursuits. Her main complaints now are chronic dyspepsia, rheumatism, and muscular weakness. A routine physical examination shows no marked abnormality, apart from the poor general development, except obvious atrophy of the small muscles of the hands together with periarticular swellings of finger joints, and gastric symptoms of discomfort, sourness and belching after meals. There has been no history nor evidence of recent infections. Teeth, throat, tonsils, ears, nose, and genito urinary tract are apparently normal. No examination of gastric contents made at the time the hygienic data was tabulated.

The series of hygienic tests and measurements show a curve given in the first chart. This line runs generally below the average and sinks especially low at the points of lung capacity and amounts of fluids taken daily. There is a corresponding small volume of urine of rather high specific gravity. The patient was interested in seeing the graphic record, and could appreciate more readily from it the necessity for increasing if possible her lung capacity, also the desirability of getting more fresh air, and of taking more water. She has been given a few breathing exercises, and she rests an hour in bed in a room with open windows, after work, just before the heavy evening meal. A few tonic medicines and milk of magnesia have helped to relieve gastric symptoms, and by these various therapeutic measures the joint pains have diminished, her appetite improved and her strength has increased. It is not to be expected that a complete cure of such a case can be accomplished quickly after the condition has slowly come on in such a life-long delicate constitution, but the graphic method makes it possible to show to patient and physician clearly in a general way what needs to be done and what is being accomplished. In the past, in this particular instance, lack of such a method has been responsible apparently for the overlooking of the quantitative physiological defects which have been producing the anatomical abnormalities in the joints.

The second chart is of a healthy woman who is a sister of the first patient. The curve is different particularly because of the higher levels for body weight and amounts of fluids taken; but it shows a lung capacity of rather low degree like the patient.

The third record is one of a patient suffering with chronic gonorrheal arthritis. A general physical examination showed nothing very remarkable except the urethral infection. In the past the patient derived much temporary benefit from a course of baths at Hot Springs, Arkansas. After returning home, however, he was unable to take care of himself and the joint symptoms came back again. Then a trial of gonorrheal vaccines was made.

Vaccines, which were continued for a long period, produced slight relief at first, but later they wore the patient out so that he was worse than when he began this treatment. He also tried various rheumatic remedies.

When first seen by the writers he presented the condition so often seen in chronic patients, namely, the effects of too much and too varied therapeutic measures. After seven or eight months' rest from all stimulating or depleting procedures, and with observance of a few hygienic regulations, joint swellings and pains have

subsided greatly, muscular strength has partially returned, seven or eight pounds have been gained in weight and a secondary anemia has disappeared.

The curve which is shown was taken at this later period, and it does not demonstrate such striking deviations as that of the first patient. This single record, by itself, is of value mainly in revealing the absence of striking abnormalities. But if a record had been taken eight months ago, it would differ sufficiently from the present one to point out tendencies of the change taking place in favorable directions. Here again the value of greater precision and greater clearness of graphic representation of clinical data is obvious.

The fourth record is one of a healthy man who does little muscular work, and who leads an ordinary sedentary life. The curve in this case runs more frequently above the base line, and its general level is higher. The fifth chart is that of his wife, who has well-defined rational ideas about personal hygiene, and who is frequently engaged in showing others how to take care of themselves. In spite of all precautions, she slowly succumbed to a very obscure metabolic type of joint disease. Physical examinations have revealed nothing definitely abnormal, and now it is considered that she represents a type of disturbance analogous to gout. There may be in her case a backing up in circulation of some unrecognized substance, perhaps creatinin in too large amounts, and this normal product of metabolism may be producing pathological changes in the joints because of excessive amounts in the blood, similarly as excessive amounts of circulating urates produce pathological anatomical changes in gouty patients.

The sixth chart shows another infectious arthritic case originally of gonorrheal origin. Specific blood tests now are negative in reaction, and apparently the patient simply is in a run-down state. He has lost greatly in weight, and arthritic involvements are extending to new parts.

He has a history of having lived very well, has eaten heartily, worked hard, and has used some alcoholic stimulants. He exhausted himself finally and then tried unsuccessfully to restore his depleted vitality with bath and tonic treatments. At the time the hygienic data were taken he could barely walk with crutches, and ankle and knee joints were swollen and sore.

The curve is valuable in showing an individual generally below the average and without any marked abnormalities. The line rises above the base line only at two related points. He has been drinking water freely so that the amount of daily fluids taken and the volume of urine are above the line of averages. The urine represents the clear pale type of low specific gravity in latent chronic interstitial nephritis.

Such a chart helps to explain why there is so little chance of any single remedy, new or old, being found that will fit all different needs of the situation. It is difficult to conceive of any single drug or therapeutic measure being discovered, that will produce readjustments in all deviating factors correctly and in exactly right degrees in each to restore the most healthy complex proportions among them all. The only imaginable way that success can be attained in such a generally depleted condition is by means of a number of therapeutic procedures, each prescribed in individual ways with definite observations upon their separate effects. A graphic chart permits these combinations and slight variations to be estimated in the best manner.

DISCUSSION OF SOME OF THE ADVANTAGES AND LIMITATIONS OF THE METHOD.

The six illustrations that have been given hint at some advantages of the method, *e.g.* that patients' interests are aroused and sustained better; that greater precision and more completeness in estimation of patients' conditions become possible, and that therefore greater success in treatment results.

Many persons will see the defects of the scheme and some possibly will condemn the whole of it because there are many faults. For the latter an explanation is necessary,—that defects, although great, are less than those which are associated with total absence of hygienic data, as quite commonly is the case now with orthopedic patients. The method has not the accuracy of comprehensive physiologic experiments conducted in institutions, for example, like the Carnegie Nutrition Laboratory in Boston; and it is intended to be intermediate only between such careful scientific labors and the neglect, due to lack of time, shown frequently now among busy practitioners.

Criticisms can be advanced that the list of measurements is very incomplete, and that it does not include many important physiological functions. This is true, and if the number of individual tests was extended the curves would possess much more significance. As previously suggested, it would be advantageous to have all normal functions represented; but the element of ease has to be reckoned with, and the writers have selected only a few representative tests, that take but a few minutes of a physician's time. It may seem advisable perhaps in the future to add others, such as blood cell counts, ages, etc.; yet as now presented the records harmonize well in the degrees of reliability, which individual tests have shown and the significance which they possess in combination.

An objection may be raised that amounts of food vary greatly from day to day with varying appetites. However, experimentally it has been found that, rough as these measurements are, they are more precise than statements of patients. One individual may claim to have an unusually good appetite and to eat a large amount, and upon weighing the food it has been discovered occasionally that the reverse condi-

tion of affairs exists. Again another person says the appetite is poor and yet not infrequently the consumption of food actually is found to be excessive. These results of food weighings should be interpreted only to point out gross tendencies, and further weighings should be made to determine the lesser degrees and changes.

It is to be noted that work of weighing the food is relegated to patients themselves. Each is provided with a pair of scales with directions for weighing and eating each kind of food separately, and practically it has been found that the task arouses patients' interests, while simultaneously relieving the physician.

Regarding the accuracy of averages, it should be explained that only great deviations are to be considered significant in interpretation of results, so that these average figures do not have to be accurate to be useful. They depend upon so many elements that they can be only very roughly approximate; for example, body weights depend upon age, sex, occupation, etc., and vary within wide limits.

These figures, nevertheless, serve as a convenient *fixed base line* for comparisons. The two tests for muscular strength, *e.g.* the strengths of the forearm muscles and of pectoral muscles, are very incomplete, yet are better than descriptions of "poor," "ordinary," and "good," as these adjectives are used often in reference to muscular development. Moreover, patients find it interesting to watch the changes from time to time in degrees of muscular weaknesses of which they complain.

Averages do not have much significance for these particular tests unless many corrections are applied, and they are of use mainly as fixed points upon the base line of the table. This fact is made more clear by a statement of D. A. Sargent, director of the Hemenway Gymnasium at Harvard University, who has very kindly informed the writers that he has found that the average strength of forearm for the male is 55 kilos and for the female 25 kilos, while the average strength of chest for the male is 65 kilos and for the female 30 kilos.

No records are given in the article with repeated observations upon the same patient over extended periods. Single charts, however, differ greatly from each other and help to show the peculiarities which each patient exhibits. This fact justifies an early paper explaining the method.

It does not seem appropriate to discuss further the significance of hygienic measures in their relation to orthopedics, because everyone understands that personal hygienic regulations mean vascular regulations, and that the latter are matters of extremely great importance in restoration of health of all tissues including bones and joints.

Orthopedics, as it is understood at present, deals at times with surgery, mechanical supports, corrective apparatus and internal medical measures in treatment of joint diseases, deformities and various anatomical weaknesses.

In progress it is recognized by every one that orthopedists must continually study their problems carefully in order not to lay too much or too little emphasis upon any one of the related, important phases of their specialty. Care has to be taken not to stretch surgical methods to limits beyond which they are more harmful than useful, nor to use them too exclusively. There has to be avoidance of the error of ascribing all benefits observed to them, or to mechanical supports when the latter are matters of greatest interest; for there always are existent less easily recognizable, and perhaps even more important, vascular peculiarities; vascular states can be regulated properly only through attention to personal hygiene.

It can be said with truth, that surgery and mechanical therapeutic devices are simply aids, that are needed only occasionally to help personal hygienic regulations restore the health. The facts are, that sometimes surgery is indispensible, and at other times artificial supports are absolutely necessary, while vascular and hygienic conditions must always be compatible with health or otherwise the other measure will fail.

TABLE I

Medical Progress.

REPORT ON OBSTETRICS.

BY ROBERT L. DENORMANDIE, M.D., BOSTON,

AND

JOHN B. SWIFT, JR., M.D., BOSTON.

(*Concluded from page 729.*)

PHARMACOLOGIC ACTION OF ECBOLIC DRUGS.

Feeling that the general practitioner has not been able to keep in touch with the recent advancement in the chemistry and pharmacology of the ecbolic drugs, Lieb[7] has reviewed briefly the more important papers, and gives the results of his own experiments on the use of oxytocics in the circulation and on the isolated uterus, and indicates their therapeutic employment.

Dogs anesthetized with morphine and chloretone were used for the blood pressure experiments and the isolated uterus of the guinea-pig was used for the experiments on the effects of oxytocics on the uterus.

A careful description of the method used accompanied the article, including some excellent

drawings and some of the blood pressure tracings.

Ergotoxine, isolated from ergot first by Tanret and later by Kraft, Barger and Carr, injected intravenously into a dog in doses of 1 mg. per kilo, causes almost immediately a pronounced rise in blood pressure with a considerable slowing and weakening of the heart. The rise occurs in a cat whose brain and spinal cord have been destroyed. It is, therefore, independent of the central nervous system and must be of peripheral origin.

Barger and Dale conclude that ergotoxine first stimulates and then paralyzes motor myoneural junctions and that this action is limited to those nerve endings which are connected with the true sympathetic system.

Therapeutically an isolated guinea pig's uterus treated with ergotoxine shows an increase in the rate and strength of contractions.

Ergotoxine used during labor has not been satisfactory. The pains are much more intense but much less persistent.

These therapeutic experiments suggest that ergotoxine does not represent the full action of ergot. Furthermore, the rise in blood pressure which follows the injection of an ergot preparation is much greater than can be explained by the ergotoxine present in the preparation. This blood pressure rise is due to several amines, the most important of which is para-hydroxyphenylethylamine. This causes a sharp rise in the blood pressure due to vasoconstriction. On the isolated uterus it may cause an increase in the rate of contractions or in addition a more complete contraction and a distinct increase in the tonus. Used therapeutically it seems to show a sharp but very transitory rise in the blood pressure, especially in patients in collapse when the rise in blood pressure was very short. It seems to have no effect on the frequency or strength of the contractions of the parturient uterus.

Ergotoxine and para-hydroxyphenylethylamine account for the effect of ergot preparations on blood pressure but do not explain the striking action on the uterus. This is believed to be due to beta-imidoazolyethylamine. This substance produces an immediate and prolonged fall in the blood pressure associated with peripheral vasodilatation. On the isolated uterus in concentration of a 1:600,000, it produces a marked contraction with cessation of rhythm in maximal tonus. Used during labor, doses of 1 to 2 mg. led to respiratory disturbances and convulsions with only a slight stimulation of the uterus.

The action of Galenical preparations of ergot may be explained as follows: The initial fall in pressure which often occurs after their intravenous injection is due chiefly to the beta-imidoazolythylamine, partly to the isoamylamine; the marked and prolonged rise is due almost entirely to the para-hydroxyphenylethylamine and only in small part to the ergotoxine. The action on the vaso-motor nerve cells and the bluing of the cock's comb are due solely to ergotoxine. The action on the uterus is referable to the ergotoxines, the para-hydroxyphenylethylamine, but essentially to the beta-imidoazolythylamine. There are also many other substances present, some of which are depressant, others inactive; chemical standardization of so complex a drug is out of the question. A well known English firm has put upon the market a preparation which is of constant composition. It consists of a certain amount of ergotoxine, obtained from ergot, to which are added definite quantities of synthetic para-hydroxyphenylethylamine and beta imidoazolythylamine.

Pituitary Extract. The intravenous injection of an extract of the posterior lobe of the pituitary gland is followed by a rise in blood pressure and a slowing and weakening of the heart. The slowing and weakening of the heart is due to direct stimulation of the vagus center. The rise in blood pressure is due to vasoconstriction, the drug acting directly on the muscular coats of the vessels. Diuresis is secondary to the rise in the blood pressure but a second dose does not increase the blood pressure but does increase the diuresis, so there must be some substance in the extract which directly stimulates the kidney cells.

On the isolated uterus pituitary extract 1:600 causes very complete contractions and then tetanus, broken by incomplete relaxations. Injected into pregnant animals, it produces abortions. Injected into a lactating animal a prompt secretion of milk follows probably due to stimulation of the smooth muscle of the breast, as the total quantity of milk secreted in twenty-four hours is not increased.

The active principle of pituitary extract has not been identified. Experiments would indicate that its action on the uterus is due to a substance closely resembling or identical with beta-imidoazolythylamine. Pituitary extract may be applied locally to stop oozing hemorrhages or to reduce congestion of mucous membranes. It is chiefly indicated in uterine inertia. It is said to be more valuable than ergot in post-partum hemorrhage and subinvolution. The chief dangers associated with its use are uterine tetanus and rupture, and fetal asphyxiation and impaction. It is contra-indicated in cardiac disease or arterio-sclerosis when an abrupt rise in blood pressure would be dangerous.

It is readily destroyed by the alimentary ferments, hence it must be used subcutaneously or intramuscularly when stimulation of the uterus, kidney, and bowel result. Injected intravenously, it produces a prompt but transitory rise in blood pressure, slowing of the heart, diuresis and uterine stimulation.

Quinine. On the isolated uterus quinine

1:100,000 caused an immediate increase in the rate and strength of the contractions, with the tonus moderately improved, an increase of the concentration to 1:25,000, threw the uterus into spasm, which later showed signs of poisoning and then death. To induce labor quinine is administered in doses of from 0.5 to 1 gram. Maurer believed that in 87% of his cases he could ascribe to quinine a pronounced ecbolic effect within forty minutes of the first dose. Failures are probably due to either lack of absorption or to depression of the uterus from excessive doses.

Iso-quinolines. This group is composed of hydrastine, narcotine and landanosine, alkaloids having a strychnine-like action on the spinal cord.

Hydrastine is the least toxic of this group. In the author's experiments hydrastine produced a marked and prolonged fall in blood pressure without preceding rise. On the isolated uterus, solutions of 1:50,000 produces a temporary cessation of rhythm in maximum tonus soon broken by comparatively large relaxation. More concentrated solution after momentary tetanus causes death of the uterus in extreme relaxation.

Hydrastinine is less toxic than hydrastis with the same pharmacologic action.

Cotarnine, marketed under the name of stypticin or styptol is derived from narcotine.

Intravenously in doses of 5 mg. per kilo there is a momentary fall in blood pressure followed by a slight rise. The heart rate is unchanged. On the isolated uterus, there is an increase in the rate of contraction and in tonus.

Therapeutically the drugs can be employed in menorrhagia and metrorrhagia, though it has been suggested that they might be of value in post-partum hemorrhage. The drugs stimulate the uterine muscles directly, the organ contracts as a whole, the lumen of the intramural vessels is obliterated and the bleeding stops.

Viburnum. Small amounts of the fluid extract of viburnum caused a considerable increase in the rate and an improvement in the tonus of the isolated uterus.

Sodium valerianate failed to produce any stimulation on the uterus and in high concentration proved distinctly toxic. Its sedative action cannot be due, therefore, to its action on the uterus. Presumably it quiets the irritable central nervous system and the uterus is affected secondarily. Apparently its use is purely empiric.

His conclusions are as follows:

1. Ergot owes its pharmacologic action to several constituents; of these, ergotoxine alone is specific. Beta-imidoazolythylamine, parahydroxyphenylethylamine and the other sympathonimetic amines are products of the putrefaction which occurs during the manufacture of the Galenical preparations. Each constituent has a distinct pharmacologic action; stimulation of the uterus is characteristic of them all. In obstetrics at least no single active principle can replace active preparations of whole ergot.

2. Extracts of the posterior lobe of the pituitary gland stimulate all smooth muscle. It has been suggested that the active constituent of the infundibulum is the hormone which initiates normal labor. The extract of the pituitary is the most reliable ecbolic which the obstetrician has at his command. Its promiscuous employment during labor cannot be too strongly condemned.

3. Because of the stimulating action of quinine on the isolated uterus it may be employed to induce or strengthen labor pains.

4. The improvement that follows the use of iso-quinolines in menorrhagia and metrorrhagia is due not to changes in the circulation or in coagulation time, but to a direct action on the uterus.

5. Fluid extract of viburnum stimulates the isolated uterus. Its action in dysmenorrhoea is therefore not due to an effect upon the uterus, but to a depression of the central nervous system.

PUBIOTOMY VERSUS CAESAREAN SECTION IN INFECTED CASES.

Rongy points out that a great deal of the work of the consulting obstetrician is in those cases where there is dystocia, due to disproportion of the size of the fetal head and the pelvis, in which attempt has been made at delivery by the general practitioner, and in which asepsis and antisepsis has not been scrupulously observed.

There are three methods of delivery at our command. First, high forceps; second, Caesarean section; third, pubiotomy. He believes that high forceps in the light of our present surgical knowledge is hardly justifiable, especially in primiparae. The effect on the mother is bad. Most of the plastic operations are a result of badly managed forceps cases. It is the only procedure in surgery where an attempt is made to pull a mass through an opening too small to admit of its easy passage without first enlarging the opening, or making the mass smaller. Its effect on the child is too well known to need discussion. Accordingly, we are left with either pubiotomy or Caesarean section.

Here Rongy distinctly states that he is not attempting to place pubiotomy in competition with Caesarean section. Pubiotomy he regards as an operation of emergency and not of election. He believes that pubiotomy is the only operation in border-lines cases that have been mismanaged or misjudged. It adds but little additional risk to the mother. The head should be somewhat engaged and forceps should have

been attempted and if then the child is alive, pubiotomy should be performed. He has followed the technic of Döderlein and he reports in detail nine cases in which he has done the operation. He feels that the operation should not be attempted except by a carefully trained gynecological surgeon as the injuries to the soft parts, the bladder and the urethra may be quite extensive. The sacro-iliac joint may be injured and if this possibility is not born in mind, permanent disability may result. Hemorrhage may be profuse. Communicating vaginal tears may take place. However, in cases that have been misjudged and neglected, with the child still viable, it is the only method of procedure, and only an experienced obstetrician should undertake its performance.

His conclusions are as follows:

1. A close study of statistics of Cesarean section of various operators compel us to assume that cases which are brought into the hospital with a history of a long and tedious labor, who were frequently examined or where delivery by forceps has been attempted, are supposedly infected and therefore abdominal section should not be the operation of choice.

2. In such cases pubiotomy becomes the operation of necessity, for it adds very little danger to the mother and it saves the child.

3. Pubiotomy is not an operation of election.

4. Cesarean section and pubiotomy never compete. In cases when Cesarean section is indicated, pubiotomy is contraindicated and vice versa.

THE TREATMENT OF THE TOXEMIA OF PREGNANCY WITH THE SERUM OF NORMAL PREGNANT WOMEN.

After suggesting the possibility of the use of serum obtained from normal pregnant women for the treatment of toxemias of pregnancy, the author[9] states that he has recently been injecting the serum intradurally rather than intravenously in cases of eclampsia. He was led to do this by the picture of severe poisoning of the central nervous system which the eclampsia presented. He has also tried the serum in cases of puerperal sepsis since many puerperae have hemolytic streptococci in their lochia without themselves being sick. One can assume that theoretically their serum is the same as that of convalescents. Three of his septic cases treated with injection of serum showed that this treatment had a bearing on the result.

PUERPERAL INFECTION.

Watkins'[10] paper is a summary of his experiences of one hundred cases of puerperal infection covering a period of eight years since operative interference was given up by him. Of these cases ninety-one recovered and nine died. Watkins feels that the attempt to classify puerperal infections complicates the study of the disease and the classification is of scientific interest but not of practical value.

The disease is essentially systemic and has ceased to be a local one when fever is present. He feels that the bacteriologic examination of vaginal and uterine secretions is of relatively small value as the results are often uncertain and misleading. The clinical findings usually determine the diagnosis, and if one relies entirely on the laboratory diagnoses by the examinations of the secretions the danger of making the wrong diagnosis is great.

Watkins says the important part of the treatment of puerperal infection is the use of remedies to increase the body resistance and the abandonment of measures that interfere with the development of immunizing substances. Food, sleep and good elimination are essential. The outdoor treatment is the most valuable remedy known in the treatment of puerperal infection. To promote elimination two quarts of fluid is the minimum amount given. Stimulants are not used. Anodynes and hypnotics are given in moderation to relieve pain and to procure at least six hours of sleep. An ice bag is kept over the lower part of the abdomen and the head of the bed is elevated to promote drainage. He says vaginal and intrauterine douches and medicinal applications are harmful, meddlesome and useless procedures. Retained products of conception should be left to escape spontaneously except in cases of hemorrhage, when gauze packing should be used to hasten separation of retained tissue. Pelvic exudates usually disappear entirely by absorption; only the exceptional case requires incision and drainage. Suspected cases of free pus in the abdominal cavity Watkins believes should have an exploratory vaginal section to determine the diagnosis and the indications for treatment.

Reports of Societies.

BOSTON SOCIETY OF PSYCHIATRY AND NEUROLOGY.

MEETING OF FEBRUARY 19, 1914, AT THE BOSTON MEDICAL LIBRARY.

D. H. FULLER, M.D., Secretary.

DR. J. W. COURTNEY read a paper entitled,

ON TERRITORIAL AUTONOMY IN CEREBRAL CIRCULATION AND ITS RÔLE IN THE GENESIS OF SYMPTOMS IN THE PSYCHONEUROSES.*

DISCUSSION.

DR. G. L. WALTON: It may at least be claimed for this theory that no more satisfactory one is at present forthcoming. As the reader has said, the expressions, "dissociation of personality," and the like, do not really go far towards explaining the symptoms under consideration. Again, when I presented the subject at the American Neurological Association in the paper to which Dr. Courtney refers in courteously crediting me with advancing the vasomotor theory, a favorite recourse of the disputants seemed to be the word "dynamic," as explaining the cerebral changes in hysterical monoplegia. This explanation also is vague and unsatisfactory, and presents nothing of which we have a recognized analogue in other parts of the body. There is a certain fascination in the proposition that separation of neurones may explain these transitory disabilities, but this is another purely theoretical proposition and on the whole less satisfactory than the vasomotor theory. It may fairly be assumed that: (1) Psychic processes are capable of producing mechanical changes in the organism. (2) The best recognized of these mechanical changes are vasomotor changes, of which need only be cited the pallor of fear and the blush of shame. (3) Such vascular changes certainly do occur at the periphery in hysteria, offering a visible analogue of the cerebral changes suggested in this theory. (4) The vascular changes in the periphery are hardly capable of explaining the symptoms under consideration, for hysterical anesthesia indicates not a simple loss of sensation, such as appears when the foot falls asleep, but involves a false interpretation which means cerebral disorder.

Dr. Courtney has added to the weight of the theory by citing recent advances in cerebral vasomotor control. At the time I presented the subject in 1884 it was assumed in my postulate that such vasomotor control existed, though there was at that time no tangible evidence to verify the supposition.

DR. A. MYERSON: Dr. Courtney's paper divides itself easily into two parts, one as to whether or not there are autonomic vasomotor centers in the brain, and secondly, whether vasomotor disturbances of a territorial kind are the cause of hysterical phenomena. For the first question, I think the answer is as Dr. Courtney has indicated, "Yes, there are such centers." Both by the experiments he has quoted, by analogy and by inference, we have a right to assume the existence of territorial regulation of the blood supply of any part of the brain. For the second question, the answer is not quite so certain. Dr. Courtney's explanation is simple, but it is almost too simple. Associated with the explanation are such obstacles as seem to me to be insuperable.

First of all, the mere fact that in the paralyzed limb of a hysteric, there is pallor and evidence of vasomotor disturbances, as well as paralysis, shows nothing concerning the origin of paralysis and its relationship to vasomotor disturbances. In the paralyzed limb of a patient suffering from anterior poliomyelitis, there are vasomotor disturbances, but no one assumes that the vasomotor disturbances have caused the paralysis. It is well understood that they are coincident and have a separate injury for their origin, a mechanism which is impaired at the same time that the motor cells are injured. So in hysteria, it may well be that the vasomotor symptoms are mere accompaniments and stand in no causative relationship to the other symptoms.

Secondly, if a cerebral spasm and anemia is responsible for paralysis in hysteria, that spasm lasts as many years, for example, as the paralysis, and then it is inconceivable to me that no permanent damage is done, that recovery can be complete and quick. Any part anemic for years, especially nerve cells, must be permanently damaged no matter what the cause of the spasm, and the limb which such cells innervate, would suffer correspondingly. The transiency, changeability of symptoms in hysteria makes the vasomotor explanation plausible until one looks deeper and then inadequacy appears.

Third, if vasomotor spasm or injury be responsible for symptoms, how does it then happen that the paralysis of hysteria practically never follows the known physiologic innervations, that it never corresponds to the cortical innervation, or peripheral nerve distribution, or the segmental arrangement, as in the spinal cord? It corresponds to an idea, the well-known glove paralysis or anesthesia. It includes surfaces not influenced in organic diseases. It is not accompanied by changes in the reflexes, such as organic diseases involving known territories bring about. In other words, it has no known relationship to territories as we now understand those territories. While the future may bring us knowledge of territorial innervation which we do not now possess, present-day theories cannot base themselves upon the future. Finally, as a pathologist, I sincerely seek physical explanation of mental phenomena. Vasomotor disturbance as a cause for hysterical symptoms appeals, but as I said at the commencement, its defects as an explanation are too apparent for my acceptance.

DR. C. K. RUSSELL: Regarding the characteristic distribution of the loss of sensibility in hysterics, namely, that which has been descriptively termed stocking or glove anesthesia, it may be of interest to refer to two patients who came under my observation when an interne at Queen's Square, in order to show that this distribution may not be merely due to the patient's conception of segmentation in the limbs. The first case I had the privilege of observing with Dr. Gordon Holmes; the second was under my own charge, and was very similar to the first. Both were cases of Jacksonian epilepsy, with the convulsions beginning in the left hand and face. Following the convulsion, in which there was little or no loss of consciousness, I noticed that besides the motor weakness of the affected side, there was a distinct loss of sensibility to pin prick

* See page 745.

extending over the half of the body and the corresponding limbs, a hemianalgesia. The recovery from this loss of sensibility was peculiar in that it began to be recovered from on the body, starting from the outside and progressing towards the midline in concentric circles. About the same time as it began to recover on the trunk, recovery was also noticed on the foot and at the shoulder, and progressed up the leg and at the same time down the arm, the hand from the wrist taking a relatively longer time to recover its sensibility. Observations following several attacks all corresponded in showing the same method of recovery of sensibility.

The results of brain disturbance which produce the march of a Jacksonian fit evidently, I imagine, are recovered from in a similar manner to that in which they are affected, viz., in receding concentric circles.

NEW ENGLAND PEDIATRIC SOCIETY.

The twenty-ninth annual meeting was held in the Boston Medical Library, Jan. 23, 1914. C. A. PRATT, M.D., President; FRITZ B. TALBOT, M.D. Secretary.

DR. CHARLES G. MIXTER read a paper entitled

A CASE OF LYMPH CYST OF THE MESENTERY.*

DISCUSSION.

DR. J. L. MORSE: I would like to speak of just one case which was on my service at the Children's Hospital, I think two years ago, which gave all the physical signs of a cyst of the mesentery, and which was, for all practical purposes, a cyst of the mesentery. It occurred in a small boy whom we had seen a year previously with tuberculosis of the mesenteric glands. In the course of the year these had broken down and he had a cold abscess about the size of an egg-plant which gave all physical signs of a cyst. Dr. J. S. Stone operated and removed it *en masse*, with good recovery.

DR. MAYNARD LADD read a paper entitled,

THE INFLUENCE OF ALKALIES ON THE GASTRIC MOTILITY IN INFANTS.**

The paper was illustrated by lantern slides of serial radiographs. Three infants were studied. Lime water in proportions of 25 and 50% of the total mixture, and bicarbonate of soda and citrate of soda, 2 grains to two ounces of the feeding, were given. The presence of lime water appeared to hasten the emptying time of the stomach by from one to two hours, if the casein was in the form in which it naturally occurs in milk. On the contrary, when the casein had been previously precipitated the addition of lime water had no material effect upon the gastric motility. Sodium bicarbonate had much the same effect as the lime water. Sodium citrate showed the least effect upon motility; its action was not at all marked. The rate at which the stomach emptied itself in the first two hours of digestion was only slightly accelerated, both with the lime water and the bicarbonate of soda, the effects of the alkalies being exerted chiefly in the latter part of the digestive period, probably due to their action in breaking up the casein curd so that the gastric protein digestion could proceed under the same favorable conditions provided in the case of precipitated casein mixtures.

DISCUSSION.

DR. J. L. MORSE: It is a pity to let such good work as this go by without saying something about it. I do not know whether all the gentlemen here realize how much confusion and uncertainty there is about the action of alkalies on the digestion of casein and the emptying of the stomach. If they did, they would appreciate better how important this work is and how much it may help us. Dr. Ladd has called attention to another important point and that is the question of the net energy value of the protein in relation to the time required for its digestion. As far as I know, no one has ever spoken of this point before, although Chapin of New York has called attention to the difference in the net energy value of the sugars, that of malt sugar being greater than that of milk sugar and cane sugar. Another point which he has brought out is the action of fat on the emptying time of the stomach. These results are rather surprising, as they are noticeably different from what we have learned as to the action of fat on digestion in adults.

DR. JOHN LOVETT MORSE read a paper entitled,

INFANTILE SCORBUTUS.

There has been both an absolute and relative increase in the number of cases of scurvy coming to the medical out-patient department of the Children's Hospital during the last few years. The per cent. of cases of scurvy to the total number of new cases during the last ten years is as follows: 0.11, 0.43, 0.17, 0.33, 0.24, 0.24, 0.47, 0.61, 0.67, 0.87. Analysis of the cases showed that 20% were fed on condensed milk or proprietary foods mixed with water. The milk was heated in at least 81% of the cases in which it was used either with or without proprietary foods. It would seem from these figures that proprietary foods, "stale" foods, or the heating of milk to the temperature of pasteurization or higher, may all play a part in the etiology of scurvy. The proportion of babies fed on the proprietary foods in 1913 was much smaller than in 1905. Boiling of the milk was much more common in 1913 than in 1905. Further analysis of the cases showed that the percentage of pasteurized milk used in Boston has increased very rapidly during the last six years coincident with the increase in the number of cases of scurvy. The figures are as follows:

Year.	Percent. of Cases.	Percent. of Pasteurized Milk.
1908	0.24	33.58
1909	0.24	30.68
1910	0.47	63.50
1911	0.61	73.02
1912	0.67	70.59
1913	0.87	80.00

* This paper was published in the JOURNAL of April 2, 1914, p. 536.

** Published in the JOURNAL of April 2, 1914, p. 518.

This, of course, suggests, but does not prove, some relation between the pasteurization of milk and the increase of cases of scurvy.

Analysis of the symptomatology of the cases showed that crying on handling was the first symptom noted in 69 cases, and paresis in 11. Tenderness of the legs and crying on being handled was found in every case, swelling in 25, paresis in 23, rigidity in 15 and inflammation of the gums in 37. The errors in diagnosis were numerous, which shows that in spite of all that has been written and said about infantile scorbutus during the past fifteen years, many physicians are still unfamiliar with the disease or unable to recognize it.

DISCUSSION.

DR. MAYNARD LADD: A good many children are practically getting a pasteurized or a boiled milk when, according to the history given by the mother, they are being fed on raw milk. I have seen three or four perfectly definite instances where, according to the mother's statements, the children were taking raw milk, and yet the children unquestionably had scurvy. Going into the cases farther, I have found that it was the custom of the mothers to take the bottle of milk, put it in boiling water, then prepare the child for the feeding, change the diapers tuck it up carefully, and then take the milk from the boiling water and cool it down to the proper temperature. That is a way of boiling milk, or pasteurizing it, which we do not ordinarily appreciate, and which I believe accounts for many cases of scurvy in babies who are fed supposedly on raw milk. Personally I believe that long-continued use of a milk pasteurized at a high temperature, or boiled milk, may, in a considerable number of cases produce scurvy, but if there is any reason for the giving of pasteurized milk for a long time, the danger can be materially reduced by giving orange juice. I have repeatedly fed children for many months on pasteurized milk where orange juice given in small amounts safeguarded against any tendency towards scurvy.

DR. W. P. COLES: I would like to ask Dr. Morse if it is not true that the statement has been spread rather broadcast in the last two years since the epidemic of septic sore throat that pasteurization of milk is not harmful?

DR. R. W. HASTINGS: I also desire to ask Dr. Morse if he still holds to his own opinion expressed not long ago that pasteurization or boiling of the milk does not injure babies. I would like to say just a word on this subject. At St. Mary's Infant Hospital some years ago, I should say seven or eight there were cases of scurvy undoubtedly. They were using heated milk. For perhaps six or eight years we used the fresh milk, not heated, and had practically no scurvy. Because of the opinion very positively stated by Dr. Rosenau, and not objected to by Dr. Morse, that possibly pasteurization might not have any such effect, for the last year, beginning just about a year ago, the babies there (there have been from 50 to 95 babies all the time) have had foods which were pasteurized. We try to make that a definite pasteurization at 145 degrees for thirty minutes, with all precautions, and to the best of our knowledge there has not occurred any case that could be called scurvy during the year. So far as the experiment has gone, and it is a pretty large experiment—something over 200,000 feedings—this degree of heating has not so altered the food (the formulae varying very much, of course, in different cases) as to bring about any cases of scurvy.

DR. T. J. EASTMAN: (Dr. Morse's paper.) I was going to ask Dr. Morse if he has any idea to what temperature the pasteurized commercial milk is raised? I think they bring it up to 145 degrees, and I think it has been stated before that a percentage of 145 does not alter the characteristics of the milk, whereas the old percentage of 167 or more might alter the characteristics of the milk. The general tendency at the present time is for commercial milk to be pasteurized. The result of the lessening of the number of small dealers is for the large dealers to accumulate milk from a number of dairies and then pasteurize it before it is sold to the public. Along the lines of education which Dr. Morse mentioned it seems to me that if it is a question of the degree of temperature it might be wise to have the milk dealers informed, so that if they are going to pasteurize the milk it should be done at a low temperature.

DR. MORSE, in closing: I feel much complimented to find that some of you have read some of the things which I have written. I have felt for many years that the most important single factor in the causation of scurvy was the heating of milk, and when I was asked, two years ago, to read a paper at a meeting of the Massachusetts Medical Society on the effect of the heating of milk on babies, I started out with the idea that I was going to prove that heating the milk caused scurvy and probably rickets. On looking over the literature carefully I had to come to the conclusion, however, that there was no evidence, theoretical, experimental, or clinical, to prove that the heating of milk caused either scurvy or rickets. I have been over the literature even more carefully since then and have been compelled to come to the same conclusion the second time. In spite of these conclusions, I still feel that my own experience suggests, even if it does not prove, that the heating of milk does play a part in the causation of scurvy, malnutrition and rickets. I feel pretty confident that variations of a few degrees of temperature in the heating of milk does not make any special difference. It is comparatively unimportant whether the milk is heated at 140, 155 or 167 degrees Fahrenheit. More important changes occur if 167° F. is passed. Boiling milk has a very different effect from pasteurization. I think personally that we are going to see much more scurvy in the next five years than we have in the past because of the recent knowledge that boiling the milk makes the casein more digestible. A lot of people are going to boil milk for that reason and a great many are going to forget to give orange juice at the same time.

DR. ARTHUR W. FAIRBANKS read a paper entitled

THE ETIOLOGY OF EPILEPSY.*

* Published in the JOURNAL of April 2, 1914, p. 521.

The Italian Parliamentary Committee has unanimously adopted a report by Professor Casciani on the means of developing the thermal stations of Italy. Among these are the institution of special courses and of travelling professorships that will enable lecturers to go about to different universities carrying on a scientific propaganda.—*British Medical Journal.*

Book Reviews.

Studies in Cancer and Allied Subjects. The Study of Experimental Cancer; a Review. By William H. Woglom, M.D. Conducted under the George Crocker Special Research Fund of Columbia University. Vol. 1. Columbia University Press, New York City. 1913.

This is an imposing quarto sized volume of 288 pages, of which the printed matter of each page would easily go on an ordinary octavo page. The increased size is due to wide margins. The contents consist of chapters as follows:—

1. Brief Historical Review.
2. Attempts to Produce Tumors.
3. Earlier Observations on the Transmissibility of Cancer.
4. Transplanted Tumors.
5. Resistance.
6. Hypersusceptibility.
7. The Spontaneous Tumor.
8. Tumors of a Nature Still Undecided.
9. Therapeutics.
10. General Summary.

It is evident that the task of the author was a large one, and he has acquitted himself well, in spite of some omissions of work of importance and the inclusion of work of doubtful significance and reliability. It is worth while reading by those who wish to obtain an idea of activities and progress in cancer research. The extravagant manner of publication is to be deprecated.

Studies in Cancer and Allied Subjects. From the Department of Zoölogy, Surgery, Clinical

A collection of papers published in the same extravagant manner as the rest of the series.

Studies in Cancer and Allied Subjects. Contributions to the Anatomy and Development of the Salivary Glands in Mammalia.

A beautifully illustrated volume, similar to others of this series, containing the following papers; of interest only to embryologists and comparative anatomists.

1. A Contribution to the Anatomy of the Human Adult Salivary Glands. By Churchill Carmalt.
2. The Development of the Human Salivary Glands. By H. von W. Schulte.
3. The Anatomy of the Salivary Glands in the Lower Primates. By George S. Huntington.
4. The Genetic Interpretation of the Primate Alveolingual Salivary Area. By George S. Huntington.
5. The Anatomy of the Salivary Glands in the Carnivora. By Churchill Carmalt.
6. The Development of the Salivary Glands in the Cat. By H. von W. Schulte.
7. The Anatomy of the Salivary Glands in Some Members of Other Mammalian Orders (Marsupials, Insectivora, Rodents and Ungulates). By Churchill Carmalt.
8. The Mammalian Alveolingual Salivary Area with Special Reference to the Development of the Greater Sublingual Glands of the Pig, Together with a Review of the Literature. By H. von W. Schulte.

Urinary Diseases. By Stephen H. Blodgett, M.D. Boston: Whitcomb and Barows. 1914.

This book, as stated in its preface, has evidently been compiled in large part, from notes used by the author in his lecture for nurses. It is, therefore, a book of well-known facts connected with urinary diseases, stated simply and briefly for the use of nurses. Its nine chapters are followed by two supplementary sections, one of which is devoted to the consideration of recipes, suitable for the patient suffering from glycosuria, and the other to a tabulation of the starch and protein contents of various foods. The book is well printed on good paper, is adequately indexed, and should serve the puprose for which it was evidently written.

Genito-Urinary Diseases and Syphilis. By Edgar G. Ballenger, M.D., Adjunct Clinical Professor of Genito-urinary Diseases, Atlanta Medical College; Urologist to Westley Memorial Hospital, etc. Assisted by Omar F. Elder, M.D. The Wassermann Reaction by Edgar Paullin, M.D. Second edition revised. pp. 527, with 109 illustrations and 5 colored plates. Atlanta, Georgia: E. W. Allen and Company.

The first edition of this book, aimed "To present the fundamental principles, and to enter, at the same time, into sufficient detail when considering matters of prime importance." In other words, the book was designed to be better and more comprehensive than a quiz compend, and at the same time to stop short of the completeness and bulk of the larger text-books,—a difficult result to accomplish. It apparently succeeded, however, in its object for now appears the second edition, compelled by the many advances in our urological knowledge, during the last two or three years.

"The more satisfactory treatment of gonorrhea, vaccine therapy, Rowntree and Geraghty's test for functional activity; pyelography; the Wassermann reaction and leutin test; the cultivation of the spirochaeta pallida,

the use of the dark field illumination in the demonstration of the spirochaeta pallida, the inoculation of animals with syphilis, and the discovery of salvarsan and neosalvarsan" are some of the many recent additions to the field of urology which made this edition necessary.

The increase of our knowledge of urology both in scope and in precision, has been so enormous in the last few years that a compilation of a real text-book into one volume has greatly increased in difficulty. How impossible must it be then to put that knowledge before the medical public in 500 pages! That is the task the writer set himself, and on the whole, he has succeeded fairly well. A very brief consideration of subjects which might seem worthy of a more extensive presentation is often evident, but for the most part, the author has maintained a just perspective and has given us a book of value, a book which carries its subject up to the year of its publication.

Type and paper are of fair quality, and some of the cuts and photographs are excellent, while others are far from being so.

Dorland's American Illustrated Medical Dictionary. A new and complete dictionary of terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, Veterinary Science, Nursing, Biology, and kindred branches; with new and elaborate tables. Seventh revised edition. Edited by W. A. NEWMAN DORLAND, M.D. Large octavo of 1107 pages, with 331 illustrations, 119 in colors. Philadelphia and London: W. B. Saunders Company. 1913.

The seventh edition of this valuable dictionary does not differ in appearance or materially in size from its predecessor. The rapid growth of certain branches of medical science has demanded the addition of a large number of words and terms, particularly in the fields of serology, physiology, pathological chemistry and experimental medicine. A complete revision of the book has been undertaken and upwards of 5000 new terms defined. The volume is published as before in flexible covers, and in general it maintains its character of convenience, completeness and reliability.

Supplement to Illustrate an Operating Theatre in Private Practice. By C. HAMILTON WHITEFORD, M.R.C.S., L.R.C.P. London: Harrison and Sons. 1914.

Mr. Whiteford's original monograph was reviewed in the issue of the JOURNAL for Sept. 19, 1912 (Vol. clxvii, p. 402). This supplement has been prepared in response to requests for a plan and illustrations, which are here provided in three full-page plates. The author has also included a description of additions made to his operating theatre during the year 1913, consisting of a glove-drier, a needle for fascia and muscle, an apparatus for rectal seepage, an apparatus for maintaining Fowler's position, a surgical diet chart, and a list of instruments and linen. The pamphlet is a convenient complement to the unique and valuable original.

Pathology. General and Special. A Manual for Students and Practitioners. By JOHN STENHOUSE, M.A., B.Sc. Second edition, revised and enlarged. Illustrated with twenty-nine engravings and a colored plate. 1913.

This book is a quiz compend in pathology; essentially a book of definitions with questions appended to the various chapters. Of possible use in cramming for such examinations as might be given by state boards.

The Unexpurgated Case Against Woman Suffrage. By SIR ALMROTH E. WRIGHT, M.D., F. R. S. New York: Paul B. Hoeber. 1913.

Admitting the general premise that women are inferior to men, physically, intellectually and morally, it is manifestly unreasonable to concede equality in the matter of the ballot. This is Sir Almroth's position. The work is written in an irritatingly patronizing style, and if the opinions expressed are widespread in England, our wonder grows less at the indignation of certain men and women as expressed in the outburst of militancy through which that country is passing.

The Elements of Bacteriological Technic. A Laboratory Guide for Medical, Dental and Technical Students. By J. W. H. EYRE, M.D., M.S., F.R.S. (Edin.). Second edition; rewritten and enlarged. W. B. Saunders Company. 1913.

This edition is a marked improvement over the first one. It contains very complete directions for the preparation of media and solutions used in bacteriological work, and the methods of procedures commonly employed in bacteriological research. Descriptions of bacteria are not included. The technic for the Wasserman reaction, opsonic index determinations, complement fixation and bacteriological analysis of water, milk, foodstuffs, sewerage and soil are included. There is a chapter on the testing of disinfectants and a series of useful tables. The book is to be heartily endorsed as adequate for the purposes for which it is intended, namely, a laboratory guide for medical, dental and technical purposes.

THE BOSTON

Medical and Surgical Journal

THURSDAY, MAY 14, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

FEDERAL OR MUNICIPAL QUARANTINE.

EARLY in his administration Mayor Curley, as part of his program of municipal economy, proposed that the quarantine service of the port of Boston be transferred from the local health department to the federal government, thereby saving this city an expense of about $20,000 a year. This plan was vigorously opposed by the Boston Chamber of Commerce and by the mercantile and shipping interests generally. It was favored chiefly by various public officials. To give both sides an opportunity to express their views, a public hearing was held on April 21, before the executive committee of the city council.

Prior to this hearing, Dr. M. Victor Safford, of the United States Public Health Service, had stated the supposed advantages of federal over municipal quarantine in a communication to the daily press, from which we may quote in part as follows:—

"There seems to be an idea prevalent here in Boston that in the matter of precautions against the introduction of exotic contagious diseases, ships arriving at this port are securing or can secure from a local municipal quarantine management dispensations that could not be obtained if the maritime quarantine officers at Boston were federal officials. Those who entertain this idea do not realize the fact that for all practical purposes the control of federal officials over the management of quarantine at Boston or any other port in the United States or its possessions, is absolute.

"The two diseases whose introduction into the country by foreign commerce are at present to be most dreaded by people in this latitude are cholera and bubonic plague.

"The introduction of either of these diseases or any other serious contagious disease at Boston is a matter which concerns the whole country. Only about one-half the passengers who arrive at Boston stay even in New England. It is through officers of the public health service, acting under the direction of the secretary of the treasury, that the federal government in a supposed emergency exercises its authority to prevent such an occurrence.

"In case of suspected danger of the introduction of cholera at this port, for example, there would be immediately sent to the local quarantine station an officer of the public health service with practical experience in handling cholera. If he should deem the sanitary interests of the country to be jeopardized by the manner in which local quarantine officials were handling the situation, an order of the secretary of the treasury requiring certificates of United States public health officers as a prerequisite for the entry of ships at the Custom House would at once follow. This, however, is not likely to happen. Unless a local quarantine official be a hopeless fool, he would welcome the expert assistance which such a public health officer could furnish him. Experience has shown that on these occasions the federal medical officer has found it advisable to mitigate rather than increase the severity of the measures that a local quarantine official is inclined to impose upon commerce.

"The proposition to turn the Boston municipal quarantine establishment over to the federal government has been made by the city officials. It has not been solicited by the government. With their present power of control over local quarantines the federal authorities are entirely willing that the city of Boston and the steamship companies should bear the expense incidental to the administration of the quarantine of the port if they care to do so. Under a federal quarantine management all costs, including those incidental to the removal from ships of passengers by the wholesale, as occurred here in 1911, fall on the federal government and not on the steamship companies.

"It is well known that the municipal quarantine at Boston has been intelligently managed in accordance with requirements prescribed by the federal government. The writer, who as a United States public health officer has been in close touch with the administration of the local quarantine for ten years, is able to testify to this. He also knows that no concessions to commerce have been granted by the local quarantine officials which would not have been obtained as a matter of course from a federal quarantine management, whatever the shipping interests may think they have been getting. Under their present management and with the power of practical control now possessed by the federal government, the actual administration of either

the Boston or New York quarantines is not regarded so important from a national public health point of view as the quarantines of many other ports already under federal arrangement. There is no reason, however, why the proposed transfer of the Boston municipal quarantine plant should not be advantageous to everybody concerned. Where municipal quarantines have been transferred to a federal management, local commercial interests have never thus far made known any desire to return to previous conditions."

At the hearing these views were reiterated by Dr. Safford. The representatives of the various business organizations in opposition to the proposed change summarized their objections essentially as follows: That the present municipal administration of the Boston quarantine service is highly efficient and satisfactory; that to transfer it to federal administration might interfere with present plans for the development of the port; that New York and Baltimore maintain their own quarantine service; that decisions can be more quickly obtained from local than from national authorities; and that a change would hamper shipping interests and divert business to other ports. Among those who spoke in favor of the change were Mr. George F. Babbitt, a former Boston health commissioner, and Mr. Edward F. McSweeney, chairman of the consumptives' hospital department.

Two days after the hearing, in a letter to the public press, Mr. John A. Sullivan, former chairman of the Boston finance commission, and now corporation counsel of the city, stated effectively the views of the advocates of federal control.

"As many persons must have received the impression that the city of Boston is trying to save $20,000 a year by discontinuing its local quarantine service and transferring the same to the federal government without regard to the interests of Boston shippers, or to the future development of our port, I think it only proper to state that every objection which has been raised by the shipping interests has been stated to the treasury department at Washington and that the department has assured the city authorities that all of these objections will be met in a satisfactory manner. This assurance was given to the Mayor before he took definite steps to have the quarantine service transferred to the federal government.

"The government is willing to station an officer in Boston and clothe him with authority to adjust all matters in relation to quarantine without the delays incident to referring such matters to Washington. It has agreed to arrange for the boarding of vessels from daybreak to dark, or earlier or later, if required, an arrangement similar to the one which it has made for the port of Philadelphia, which is now under federal jurisdiction. It has also agreed to reserve at the quarantine station all existing facilities for the care of smallpox patients or persons affected with other dangerous diseases. In short, it stands ready to maintain a service equal in every respect to that now maintained at this port.

"It is true, of course, that the successor of the present secretary of the treasury might, after the Boston service had been transferred to the federal government, change the regulations to the detriment of shipping interests, but he is not likely to do so any more than Boston health officials in the future would be likely to change the regulations made by the present health officials of the city. The fact that the United States government has since 1893 waived the requirement of local inspection of vessels from Canadian ports, although it might have insisted upon such inspection during the intervening years, should be taken as a sufficient indication of the good faith of the government.

"At present only three important ports in the country are under local control—New York, Baltimore and Boston. In all the other Atlantic ports under the control of the federal government, as well as the ports on the Pacific, all of which are under federal control, the service is performed in a satisfactory manner.

"Quarantine service is not local but national in character. The national authorities have the power to follow suspected cases into any part of the United States and to isolate them for the public protection. Local authorities, whether state or municipal, have no jurisdiction beyond their own boundaries. In this respect municipal or state control of quarantine is inferior to national control. The health of the entire community should be regarded as paramount to the interests of shippers at any port; but where, as in the present case, the shipping interests will be fully protected and public health better conserved, there would seem to be no sound reason for opposition to the proposed transfer.

"It has been suggested that Boston should not take the step until New York and Baltimore have come under federal control. If New York and Baltimore take the same position all three ports will forever remain outside of federal control. If, on the other hand, Boston comes under federal control, and the service proves satisfactory, it is probable that New York and Baltimore will ask that their services be transferred to the federal government.

"Any stranger who attended the hearing at the City Council yesterday would have come to the conclusion that the shipping interests were opposing the transfer because of the ultra-conservatism which fears any change simply because it is change, or because they were now enjoying illegal privileges which they feared they

would lose if placed under federal control. The chairman of the city's Board of Health is authority for the statement that no illegal privileges are given, therefore there seems to be no reason why the shipping interests should oppose the transfer.

"Of course the saving of $20,000 or $25,000 a year is not a matter of great importance. The city can afford to waste this amount of money just as well as it could afford to waste money for any other unnecessary purpose, but if, as the hearing of yesterday clearly disclosed, the service will be at least equal to that now rendered, there ought not to be any opposition to the saving of $20,000 or $25,000 a year by the city, for there are many useful purposes for which this money is needed."

In rejoinder to Mr. Sullivan's communication, the following letter from Mr. William C. Brewer was published in the daily press of May 2:—

"The principal objection advanced by the shipping interests against federal quarantine is that it entails a final decision from Washington on any matters which the local federal doctor feels he must submit to the department. Any one conversant with departmental routine knows what delays this may entail. Under city quarantine an opportunity is given to the interested party to lay his case before the health department and obtain a ruling without any delay.

"Mr. Sullivan perhaps unconsciously supports the position taken by the shipping interests when he writes that the treasury department is willing to clothe their representative in Boston with authority to adjust matters 'without the delays incident to referring such matters to Washinton.' Does not this appear an admission on the part of the federal authorities that the argument of the shipping interests, as to probable delay, is well founded. Even further, Mr. Sullivan admits that a future secretary might modify these concessions 'to the detriment of shipping interests.' And yet the state of Massachusetts is spending $9,000,000 to develop the port of Boston. It is difficult to reconcile the attitude of the city and the state.

"It is not my desire to discuss here the relative merits of federal and local quarantine, suffice it to say, that our local quarantine is subject to federal supervisory control and regulations and that it was conceded that our city quarantine was efficient and able to safeguard the public health.

"I think that the 'fears' of our local shipping, as to any change in the present system, have some justification when the following figures of the transatlantic passengers passing through the principal ports of the United States are noted and their system of quarantine:

New York—State control	1,708,358
Boston—City control	134,318
Philadelphia—State-Federal	87,044
Baltimore—City	47,533
Portland—Federal	15,816
Galveston—State	10,459
New Orleans—Federal	1,491

"Last, and by no means least, as the proposed transfer of our quarantine is based on economy for the city, it is a fact that the arrangement suggested by the treasury department carries with it the proviso that the city shall continue to send down to quarantine and pay the federal government for their maintenance, all cases of infectious diseases and that the city shall agree to maintain a means of transportation to carry such cases to and from quarantine. It would seem as though this arrangement will still cause the city considerable expense, especially as the cost of transportation, particularly in the event of an epidemic, is problematical.

"When all the ports competitive to us pass entirely under federal control, then and not till then, should Boston seriously consider the proposition and even then we must not forget our Canadian rivals, who are advancing by leaps and bounds and successfully catering for a large share of the passenger travel."

It seems that probably both the opponents and the advocates of the change speak from a slightly biased point of view. The latter are public officials and tend to speak *ex parte;* the former, as business conservatives, are prone to object to any change on general principles. As a matter of fact, there seems no urgent need for making the change at present, and again if it were made probably no serious disadvantages would follow.

At the meeting of the city council on May 5, Mr. Sullivan requested more time to investigate the problem, and definite action on the proposal was postponed for another week.

As the JOURNAL goes to press we learn that at its meeting on May 12 the City Council rejected the proposal to transfer the quarantine, but that the plan will probably be revised in connection with the proposed reorganization of the State Board of Health.

THE RELATIONSHIP OF HYSTERIA TO OTHER CONDITIONS.

HYSTERIA is now generally conceded to be a psychoneurosis, in which the primary etiologic factor is mental. Viewing the disorder from this psychic aspect we find that hysteria has most intimate relationships to various other psychic states, normal and abnormal.

In order to understand the more clearly the relationships to which we shall refer, it would be

advisable to review here the two definitions of hysteria which have received the widest recognition. According to Binet, hysteria is a condition of double consciousness, with two streams of consciousness flowing side by side, relatively independent and separated by amnesia. Janet would define hysteria as a form of mental depression characterized by the retraction of the field of personal consciousness and by the tendency to the dissociation and the emancipation of systems of ideas which by their synthesis constitute the personality. From these two definitions as a starting point, various correlationships between hysteria and other allied conditions may be built up. The relationship between hysteria and various other states of mental dissociation at once comes to mind. And, as one would expect, this similarity did not escape the attention of neurologists, psychopathologists and psychiatrists who have concerned themselves with the problem of hysteria.

Janet tells us that to be suggestible is to be hysterical, and that only hysterics can be hypnotized. He believes in the identity of the hysterical and the hypnotic states, based upon the common factor of suggestibility. Sidis has called attention to the so-called hypnoidal state, a mental state or state of consciousness between waking and sleep on the one hand and hypnosis on the other, which is thus a semi-waking state, which is believed by Sidis to be the primitive rest state of animals, and from which both sleep and hypnosis are developed. There is thus a relationship between hysteria and the hypnoidal state, as well as between hysteria and hypnosis. Claperède reminds us that both sleep and hysteria are biological defense reactions. Bernheim asserts that the state of hypnosis is allied to that of sleep. And McDougall points out the similarities between sleep and hypnosis. Prince and others have shown the close relationship between hysteria and the cases of multiple or dissociated personalities. And latterly the results obtained by psychoanalysis have proved the intimate association of hysteria to the so-called psychopathological acts of everyday life, such as slips of the tongue and pen, acts of forgetfulness and the like. Snyder laid stress upon the naïve, simple, infantile, primitive mentality which we find in so many hysterics, and its possible relation to the infancy of the race at once comes to mind. Others have noted certain points of similarity between hysteria and mental enfeeblement.

The most important advance in this direction in the past few years has been given to us as a result of intensive studies in dementia precox. So noteworthy has been the progress that it should be touched upon at somewhat greater length. Psychopathologists look upon dementia precox as an inadequate biological reaction due to internal ideas or external experiences. It is to be noted that this conception had previously been applied to the study of the elucidation of the mechanism of hysteria. It has been found that dementia precox shows many features strongly resembling hysteria. The most prominent features of this type are the delirious episodes, the irrelevant replies to questions, the stupor, the vasomotor disorders and peculiar disturbances of consciousness. It is also known that many of the features of katatonic stupor resemble hypnosis. It was this which led Evenson to regard dementia precox as a narrowing of the field of consciousness, thus corresponding quite closely with the view of the psychogenesis of hysteria as defined by Janet. It has been discovered that both dementia precox and hysteria show phenomena pointing to a profound mental dissociation, the latter causing a curable hysteria in one case, and an incurable dementia precox in another.

In a recent paper entitled "Recent Trends in the Psychopathology of Dementia Precox," Coriat tells us that Evenson observed a close similarity between some of the prominent symptoms of dementia precox, such as negativism, stereotypy, peculiar attitudes and the reaction of a normal person who has become preoccupied by a thought. Evenson went so far as to suggest that the essential symptoms in both the preoccupied individual and in the katatonic were due to a narrowing of consciousness around a central content. He further declared that there existed a close analogy between hypnosis and katatonic stupor.

It is due, however, to the very splendid work of Jung and Bleuler, the so-called Zurich school, that the most remarkable advance in the psychopathology of dementia precox has been obtained. Jung states that the psychological mechanisms of dreams and hysteria are most closely related to those of dementia precox. As Coriat says, when the underlying complexes control the entire mental life we have dementia precox, whereas when they merely lessen the amount of energy at the disposal of the patient we have hysteria.

REORGANIZATION OF THE BOSTON BOARD OF HEALTH.

In the issues of the JOURNAL for Jan. 22 and Feb. 26 we published editorials on the "Reorganization of the Massachusetts State Board of Health." What was then said of the desirability of a single highly paid commissioner of health in authority, with an unpaid advisory board, is equally applicable to the problem of local health administration in large cities.

In Boston the term of one of the three members of the local board of health expired last month. His place has not yet been filled and the time seems opportune to consider the possibility and desirability of reorganization of the board on the basis which we have approved for the state board. In a recent letter to the daily press on this subject, Dr. Richard C. Cabot said in part:—

"Those of us who followed the work of the board of health for a number of years have reason to believe that the work of that board was never so good as it is today. Despite all of the drawbacks and political interferences to which it has been subjected, it has been and is doing a good work.

"But it ought to do far better work, and it is not at all likely to do so under its present faulty organization. It certainly ought to be a single-headed board and not a three-headed board, as at present. It certainly ought to be free to discharge or pension off its superannuated employees."

What is most important of all is that the reorganized board should be free from political control. The supervision of public health is a business, and should be administered by a competent expert for the benefit of the public.

THE AMERICAN GYNECOLOGICAL SOCIETY.

THE thirty-ninth annual meeting of the American Gynecological Society is to be held next week in Boston, and the medical profession is cordially invited to its sessions. The headquarters of the Society will be at the Harvard Club. The scientific meetings on Tuesday and Thursday, May 19 and 21, are to be held at the Boston Medical Library. Wednesday, May 20, will be spent at the Brookline Country Club.

For the morning session on May 19, four papers are announced, by Drs. Manton of Detroit, Clark of Philadelphia, Byford of Chicago, and Higgins of Pittsburgh. The afternoon session on this day will be devoted to a symposium on anesthesia. In the forenoon of May 20 will be the president's address, by Dr. J. Whitridge Williams, of Baltimore; a memorial of Henry J. Garrigues, by Dr. Brooks H. Wells; and papers by Dr. Robert L. Dickinson of New York, Dr. E. A. Codman of Boston, and Dr. Reuben Peterson of Ann Arbor. In the afternoon the principal paper will be by Dr. Wilhelm Nagel, of Berlin, on "Operative Treatment of Prolapse of the Vagina." Eight papers are announced for the sessions on May 21.

The American Gynecological Society last met at Boston in 1904. The immense progress of the past decade in medical science has affected its specialty as importantly as it has the other branches of medicine, and will be reflected in its proceedings, which will be reported in subsequent issues of the JOURNAL. The cordial welcome of the Boston profession, as well as of the local members of the Society, awaits the members from other cities and the distinguished guests.

MEDICAL LEGISLATION. THE DENTAL NURSE BILL.

IN the issues of the JOURNAL for Jan. 1 (p. 24), and Jan. 22 (p. 139) we commented editorially on the so-called "dental nurse bill," submitted to the General Court by and with the approval of the Massachusetts Civic League, providing for the appointment of a state board of dental examiners in this Commonwealth, and defining their duties. After prolonged discussion, this bill was on May 6 favorably reported to the House by the committee on public health, but with five of the eleven members of this committee dissenting. The fate of this bill in the legislature will be watched with interest by both advocates and opponents. We have only to reiterate our approval of its purpose and our hope that it may be enacted into law.

MEDICAL NOTES.

BUBONIC PLAGUE IN CHINA.—Report from China states that, during the week ended April 29, 193 cases of bubonic plague were notified at Hongkong.

A VERSATILE AND VIGOROUS CENTENARIAN.—Robert Crichton, of Caterham Valley, England, is said to have been born on April 3, 1812, at Alyth, in Perthshire, Scotland. While studying law, he served for a time as clerk to Sir Walter Scott, when the latter was sheriff of Midlothian. In 1839 Crichton sailed for Australia, and spent his active life there as a pioneer in New South Wales. Since his return to England in 1894, he has travelled extensively in Egypt, Italy, and Palestine. In 1910 he renounced his lifelong use of alcoholic beverages, having become convinced that they were injurious to his health. He continues, however, to take snuff, which he believes harmless.

COMPARATIVE MORTALITY OF MEASLES.—Statistics recently published show that the mortality of measles per 100,000 is 48 in Chile, 44 in Hungary, 38 in Spain, 35 in Belgium, 33 in Austria, 29 in England and Wales, 10.8 in the United States, 6 in Sweden, 3.4 in New Zealand, and 2.4 in Australia.

BUBONIC PLAGUE IN HAVANA.—Report from Havana states that another death from bubonic plague occurred in that city on April 30. This makes a total of 16 cases and 3 deaths of the disease since the recent introduction of the infection.

A MUNIFICENT HOSPITAL GIFT.—It is announced that Mr. James Deering, of Cleveland, Ohio, has made a gift of $1,000,000 for the endowment of the Wesley Hospital of that city, with the provision that it shall be a teaching hospital under control of Northwestern University. This munificent gift is made in memory of the donor's father and sister.

GEORGIA MEDICAL HALL.—On Tuesday evening, March 31, the new building of the Georgia Medical Society was formally dedicated at Savannah, Ga., with appropriate exercises. The principal address was by Dr. J. Ewing Mears, of Philadelphia, who spoke on "The Significance of Construction and Opening of the Medical Hall." Dr. Mears has established a foundation in the society's library for the purchase of books.

BOSTON AND NEW ENGLAND.

AN IMPORTANT OPPORTUNITY FOR RESEARCH.—Report from Washington, D. C., on May 4 states that, in response to a letter from Dr. J. Collins Warren, of Boston, Surgeon-General Blue, of the United States Public Health Service, has directed that ten beds in the Marine Hospital at Chelsea, Mass., be placed at the disposal of the Harvard Medical School, for cooperative work in the study of tropic diseases.

TRUSTEES OF BOSTON CITY HOSPITAL.—At the recent annual organization of the board of trustees of the Boston City Hospital, Mr. A. Shuman was re-elected president, and Dr. John J. Dowling, recently appointed, was duly qualified as a member.

NEW HAMPSHIRE MEDICAL SOCIETY.—The one hundred and twenty-third annual meeting of the New Hampshire Medical Society was held at Concord, N. H., on Wednesday of this week, May 13. Among the papers presented by invited guests was one on "The Conduct of a Case of Labor," by Dr. Franklin S. Newell, and one on "Fractures of the Spine and Pelvis," by Dr. Frederic J. Cotton, of Boston. Dr. George W. Crile of Cleveland, spoke on "Anoci-Association."

FOXBOROUGH STATE HOSPITAL.—The recently published twenty-second annual report of the trustees of the Foxborough State Hospital, administering also the Norfolk State Hospital, records the work and progress of these two institutions for the year ended Nov. 30, 1913. During this period the total number of inebriate patients under treatment was 1437, and of insane 237. The out-patient department, during the four years since its establishment, has followed 2261 cases. The new buildings at Norfolk were completed and ready for occupancy on Jan. 1, 1914. Among the urgent present needs of the institution is an appropriation to enable the foundation of a farm-colony for the treatment of women inebriates.

WORCESTER CITY HOSPITAL.—The recently published forty-third annual report of the trustees of the Worcester (Mass.) City Hospital records the work and progress of that institution for the year ended Nov. 30, 1913. During this period 5390 patients were treated in the wards, 23,278 treatments were given in the out-patient

department, and 1069 in the accident room. From the training-school 32 nurses were graduated. New buildings are in progress of construction for the children's ward and the nurses' home.

OFFICE OF VITAL STATISTICIAN RESTORED IN BOSTON.—In a recent issue of the JOURNAL we noted the abolition by Mayor Curley of the office of vital statistician in Boston. As a result of numerous protests, this order has been rescinded, and Dr. William H. Davis will continue to hold the position.

SCARLET FEVER AT BEDFORD.—Report from Bedford, Mass., states that 15 cases of scarlet fever have occurred in that town during the past six weeks, and that the local public schools have been ordered closed for ten days to prevent further spread of the infection.

SMALLPOX CASE IN AMESBURY.—Report from Amesbury, Mass., states that a case of smallpox was discovered in that town on April 30. The patient, who had been on a recent visit to Boston, has been quarantined, and all contacts have been vaccinated.

A LIVING CENTENARIAN.—Ralph Butler, of Dorchester, Mass., is said to have been born on May 5, 1813.

A PROLIFIC CENTENARIAN SLAVE. — Mrs. Thomas Spence, a negress who died recently in Boston, is said to have been born in 1801 at Camden, Me. She was sold into slavery, and all of her sixteen children, three of whom survive her, were born slaves. She was twice married.

WOMEN IN FOREIGN MEDICAL WORK.—The annual meeting of the Women's Medical Association for Aiding Women in Medical Work in Foreign Countries was held last week in Boston. The principal speaker was Dr. Katharine B. Scott, who has been working for several years in Madura, India. The following officers were elected: President, Dr. Emily R. Howard; first vice-president, Dr. Elizabeth E. Ritter; second vice-president, Dr. Blanche A. Denig; secretary, Dr. Marian Coon; treasurer, Dr. Helen I. Woodworth; auditor, Dr. Anna O'Sullivan; chairman of China work, Dr. Frances Morris; of India work, Dr. Alice H. Bigelow.

BROCKTON BOARD OF HEALTH.—The recently published thirty-second annual report of the department of public health of Brockton, Mass., records the activities of that body for the calendar year 1913. During this period the death-rate was only 10.88 and the birth-rate 36.23. The usual tables and departmental reports are appended.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending May 5, 1914: Diphtheria, 24; scarlatina, 93, of which 18 were non-residents; typhoid fever, 3; measles, 88, of which 2 were non-residents; tuberculosis, 58, of which 2 were non-residents.

The death-rate of the reported deaths for the week was 15.49.

NEW YORK.

AMERICAN ASSOCIATION OF MEDICAL JURISPRUDENCE.—The annual meeting of the American Association of Medical Jurisprudence was held at the New York Academy of Medicine on May 2, and among the questions discussed were the sterilization of mental defectives and medical experimentation upon condemned murderers. Dr. Charles A. Boston, a prominent member of the New York Bar, was elected president; succeeding Dr. Reynold Webb Wilcox, the first president of the association. San Francisco was selected as the place for holding the next annual meeting.

NEW CANCER HOSPITAL.—It is announced that arrangements have been effected for the control by the Cornell University Medical College of the largest cancer hospital in this country. The buildings for this are those of the General Memorial Hospital, at 105th and 106th Streets and Central Park West, an institution which was originally intended for the treatment of cancer. A fund of over $1,000,000 has already been secured, and $500,000 of this is stated to have been contributed by Dr. James Douglas, head of the house of Phelps, Dodge and Company, through whom also the hospital will receive a large supply of radium.

RESIGNATIONS AT COLUMBIA.—At the monthly meeting of the trustees of Columbia University, on May 4, the resignations were accepted of Prof. F. J. Goodnow, who has been made president of Johns Hopkins University; Dr. Theodore C. Janeway, Bard professor of the practice

of medicine; and Frederick Peterson, professor of psychiatry. Dr. J. Ramsay Hunt having resigned the professorship of neurology, Dr. Frederick Tilney, now associate in anatomy, was appointed to succeed him in that position. Among the gifts announced at the meeting was one of $500 from H. E. Sargent of Chicago for research work in anthropology.

RESULTS OF FRIEDMANN TREATMENT.—Health Commissioner Goldwater has published in the department's *Weekly Bulletin* a report of an investigation of the cases of tuberculosis treated in New York by the Friedmann remedy, showing the entire failure of the treatment. Of the total of 77 patients, 19 could not be found, while 11 were reported to have removed from the city permanently, so that nothing could be learned of their condition. The department was, therefore, able to obtain reports on but 47 of the 77 cases. The reports are summarized as follows: At home, 5; in hospitals (indicating failure to cure), 22; attending clinics (showing need of further treatment), 7; attended by private physician, 1; died, 12. The report concludes with the words, "Comment is unnecessary; the figures tell their own story."

DEATH-RATE FOR THE WEEK ENDED MAY 2.—There were 1593 deaths and a death-rate of 14.89 per 1000 of the population reported during the past week, as against 1532 deaths and a rate of 14.88 for the corresponding week of 1913, an absolute increase of 61 deaths, and an increase in the rate of .01, which is equivalent to a relative increase of 1 death. The causes which showed a decreased mortality were diphtheria and croup, cerebral spinal meningitis, organic heart disease, pneumonia, tuberculous diseases other than pulmonary, Bright's disease and nephritis, and deaths from violence. The causes showing an increased mortality were measles, scarlet fever, whooping cough, typhoid fever, diarrheal diseases under five years and pulmonary tuberculosis.

Viewed from the point of age grouping, the mortality of infants under one year of age was approximately the same, while that between one and five years of age was considerably below that of the corresponding week of 1913. The mortality between five and sixty-five years of age showed very little change over the figures of 1913, while that of the age over sixty-five years a considerably increased mortality was recorded.

The borough of Richmond showed the highest death-rate for the week, due to the presence of several large institutions, the inmates of which come from other parts of the country, and to the unfavorable age distribution of the population. The next highest rate was found in the borough of Manhattan, followed by the borough of Brooklyn, borough of The Bronx, and the lowest mortality being recorded in the borough of Queens.

The death-rate for the first eighteen weeks of 1914 was 15.43 per 1000 of the population as against a rate of 15.63 during the corresponding period of 1913, a decrease of .20 of a point.

9. Under the name "tango-foot," Boehme describes a condition which he has observed frequently of late and which he ascribes to the extraordinary flexibility of the ankle which the new dancing requires. The strain comes especially on the tibialis anticus, the extensor communis digitorum, and the extensor proprius hallucis, and the result is a teno-synovitis of this muscle group. The symptoms are stiffness of the ankle joint and pain along the outer anterior aspect of the lower third of the leg. Abstinence from dancing is often sufficient treatment, but complete rest of the foot may be necessary. Counter-irritation and baking give relief in severe cases. [L. D. C.]

4. Pfahler states that gall-stones can be shown by x-ray only when they are composed of a substance of greater or less density than the surrounding tissues. This will usually mean that they must contain some lime salts, though the quantity may be small. The author's records show positive findings in 74%, but in general not more than 50% can be counted on being positive.

8. Block finds that the effect of ether anesthesia on healthy kidneys is practically nil so far as reducing the excretory power of these organs is concerned. Traces of albumen before operation should not give much concern, but larger amounts should cause concern if accompanied by casts. The duration of anesthesia in any given case does not in itself signify the amount of injury which the kidneys will sustain. The position of the patient on the table, the character of the operation and the administration of proctoclysis have not shown any effect on the percentage of phenol-sulphonephthalein excretion after as compared with that before operation. In one-third of the cases there is increased excretion after operation.

9. Pardee's article on the use of the electrocardiogram is of value and interest.

10. Davis finds that roentgenoscopy is valuable in making a differential diagnosis of enlargement of cervical lymph nodes. This is possible only when tuberculous nodes have become necrotic and caseous and calcification later takes place. It is the calcium salt which shows in the x-ray. [E. H. R.]

6. Champtaloup, S. T. *Multiple Subcutaneous Tuberculosis Following Circumcision and Treated by Tuberculin.*
7. Jessel, G. *The Possibilities of Domiciliary Treatment in Phthisis.*

1. Thomson, in an interesting and valuable paper, finds the larynx involved in 25.6% of selected sanatorium cases; a considerable number, however,

showed *no active lesions*. This occurs much more frequently in early cases than is generally supposed. The prognosis is much worse with such a complication. There may be no symptoms of laryngeal trouble and therefore the larynx should be inspected in every case. Improvement of lung and larynx generally go on together, but rarely the larynx gets better while the lung gets worse. Arrest of this condition can be effected in 20.7% of all cases. The galvano-cautery is the best method of treatment locally, but sanatorium treatment is by far the best in all cases; local measures are far more promising in such instances.

2. This is a typical article by this well known ardent believer in tuberculin in phthisis. As usual, he reports remarkable cures of advanced cases of consumption under tuberculin and dispensary treatment. His claims are too remarkable to be taken at their face value, but in England at least, his ideas seem to be slowly but surely gaining credence. The article is of distinct interest.

4. This is a short paper based on five cases with valuable reference to the work of others on the subject. While nothing new is presented, the article is of value.

5. Neve bases his work on the surgery of tuberculous glands in 800 cases operated on in Kashmir, India; 75% were cured, but of these in 10% a recurrence might be expected. (This 10% is probably too low a figure.—J. B. H.) He emphasizes preliminary treatment of teeth, tonsils, ears, etc. In this class of patients radical measures are needed in order to keep control of the patients. Considering the class of patients, his results are remarkably good. [J. B. H.]

EDINBURGH MEDICAL JOURNAL.

APRIL, 1914.

1. *ROSS, T. A. *The Nature and Treatment of Neurasthenia.*
2. *MITCHELL, A. P. *The Milk Question in Edinburgh.*
3. *MCNEIL, C. *Scrofula or Hypersensitiveness to Tuberculous Infection.*
4. *BARCROFT, D. M. *Modern Treatment of Consumption.*
5. *WATSON, D. C. *Manifestations and Treatment of Intestinal Toxemia.*

1. This is a long and practical article on the treatment of neurasthenia and its nature. Ross discusses its symptoms, mental and physical, the need of a careful history, going deeply into underlying causes and the need of getting the patient's confidence. He discusses the work of Dubois and Mitchell and others and then goes into details of treatment, rest in bed, diet, massage, baths.

2. This article is a striking account of the milk situation in Edinburgh with valuable suggestions as to prevention of tuberculosis among cattle, and how to procure a supply of clean milk, butter, etc. He is an ardent advocate of the sterilization of milk and believes that the danger of infantile rickets and scurvy has been greatly exaggerated.

3. In this paper McNeil attempts, but without success, to describe scrofula as a definite clinical entity. He discusses the clinical features, which are simply those of the weak, poorly-nourished and tuberculous child, and evidently believes in the old saying (which has done much harm) that scrofulous children later on rarely develop pulmonary tuberculosis. According to him scrofula is something more than a variety of tuberculous infection and is allied to the status lymphaticus. (The reviewer is strongly of the opinion that such discussion as this are utterly futile.—J. B. H.)

4. Barcroft urges individualizing in each case of phthisis as to treatment. Tuberculin in experienced hands is of great value. Artificial pneumothorax is beyond the scope of general practitioners. Intensive iodine treatment is still on trial. The sanatorium is of value and particularly as an educative agent.

5. In the treatment of intestinal toxemia, Watson discusses rest, diet in great detail, treatment of the bowels, stimulation of renal excretions, hydrotherapy, massage and exercise, and vaccines. [J. B. H.]

17. GANS, O. *The Technic of Bleeding and Intravenous Infusions.*
18. OELLER, H., AND STEPHAN, R. *Clinical Studies with Abderhalden's Dialysis Method.*

2. Eskuchen has given the Swift-Ellis intraspinous salvarsan treatment in nine cases of tabes, in two of cerebro-spinal lues, and in five cases of dementia paralytica. Eskuchen concludes that by this form of treatment, the pleocytosis of the cerebro-spinal fluid was diminished rapidly, the Wassermann reaction was but slightly weakened, and that the colloidal gold test remained unchanged. Subjectively, various symptoms were quickly and markedly bettered and the progression of the disease was arrested.

13. Obmann reports the case of a child who developed fever and a generalized eruption after vaccination. In the rare similar cases which have been reported, there has been discussion as to whether this complication was due to auto-inoculation or to a general infection. Obmann believes that in his case a general infection took place, since the eruption developed in areas where auto-infection seemed impossible, and because the patient showed such symptoms of a systemic disturbance as high fever, an enlarged spleen, leucocytosis with relative lymphocytosis and inflammation of the mucous membanes of the nose and mouth. 1. Moro's original article, describing a "recurrent umbilical colic" in children, of a more or less neurotic etiology and curable by medical and suggestive therapeutics, was recently refuted by Küttner, who reported several such cases, all of which, he claims, were cured by appendectomy. In an answer to Küttner's statements, Moro reasserts his former opinions which are briefly as follows: Children are subject to these attacks; (1) the pain occurs with great regularity in the region of the umbilicus; (2) the attacks are always without fever and recur often; (3) the patients are usually hypersensitive, of a sort of angioneurotic nature, and have usually been improperly trained and brought up; and (4) they can be cured by dietetic and pedagogic reforms, together with suggestion.

2. This is another article on the above subject contradicting Küttner's statement that the appendix is the cause of this so-called umbilical colic. Friedjung had, even before Moro, described some years ago in an exhaustive article an hysteric or neuropathologic condition in childhood which manifested itself in this way. He says that the appendix is not at fault, and that he has been able to cure them with such treatment as tincture of valerian and suggestion, as thoroughly as Küttner has with appendectomy.

[R. H. M.]

Obituary.

THOMAS DRUSLYN GRIFFITHS, M.D., LOND., D.Sc. OXON.

Dr. Thomas Druslyn Griffiths, of Swansea, Wales, who died of pneumonia on April 17, in Bournemouth, England, was born at Hên Plâs, Llan-y-bythyr, Cardiganshire, in 1837. He obtained his preliminary education at the Normal College Swansea, and then was apprenticed for a time to Dr. Michael, a leading practitioner of that city. Later he entered the University of London, where he had a brilliant career as a student, winning medals in anatomy, physiology, and medicine, gold medals in botany and comparative anatomy, the Filliter prize in pathology, and the Atkinson Morley scholarship. In 1862 he received the degree of M.B. with honors in medicine, surgery and midwifery, and in the same year qualified as M.R.C.S. and L. S. A.

In 1863 Dr. Griffiths settled in the practise of his profession at Swansea, where he won an extensive reputation as one of the first exponents in Wales of the new principles of Listerism, and was the first surgeon in that country to aspirate for pleurisy. In 1872 he received from the University of London the degree of M.D. From 1880 to 1885 he served as ophthalmic surgeon to the Swansea General Hospital and was a governor of the University of Aberystwith. He published papers on the pathology and treatment of intestinal wounds, on dermoid ovarian tumors, on the causes and pathology of acquired malpositions of the uterus, and on the treatment of gastric ulcer.

In 1903 Dr. Griffiths was elected president of the British Medical Association, and in 1904 received from Oxford University the honorary degree of D.Sc. He retired in 1913, after fifty years of practice, during which he had been the foremost Welsh surgeon of his day. He is survived by his widow and by several children.

Miscellany.

A COLLECTION OF GREEK SURGICAL INSTRUMENTS.

There has recently been presented to Johns Hopkins University a very valuable set of 37 ancient Greek surgical instruments, originally discovered near the site of Kolophon, in Ionia, and for some time in the possession of the Dutch vice consul at Smyrna. These instruments, now on exhibition in England, prior to being sent to Baltimore, are thus described in a recent issue of the London *Times*.

"The instruments show a type of workmanship unequalled in any other extant specimens and generally reveal the very great progress in surgery which the ancients achieved. The date, though somewhat uncertain, is probably the first or second century A.D.; it is possible, however, that it may have been before the Christian era.

"With two exceptions all the instruments are of bronze. The blades of the knives were originally of steel, but in each case this metal has been almost completely destroyed by oxidation. Among the collection is a large 'beaker,' made of purple glass and decorated. When discovered, it was broken into fragments; these, however, have now been united. The idea entertained is that this was the drinking cup of the physician, or possibly the vessel used for pouring libations at his tomb.

"It is an interesting fact that in ancient times knives were made either of stone or bronze. This custom was followed, not because iron was unknown, but because that metal was held in superstitious fear,—a fear which lingered into the Christian era. According to Plutarch it was actually unlawful to introduce any iron implement into a Greek temple, and no Roman priest might be shaved by an iron razor or iron scissors. Surgical knives however, had steel blades. Nevertheless, even these bore, on the opposite side from the actual blade, a leaflike projection of bronze with two edges,—a survival of the earlier bronze blade, preserved, apparently, for ceremonial reasons. Each of the six knives (or rather knife handles) in the collection shows a groove for the steel blade which it originally possessed. It is probable that, as in modern instances, the shapes of the blades differed considerably to suit different operations.

"Among the five pairs of forceps is a large and beautifully made instrument, the handles of which are shaped to represent two dolphins. This is probably a pair of polypus forceps. The 'bite' of the teeth is strong and close. Another interesting pair of forceps is that used for extracting arrow and lance heads from wounds. This pair somewhat closely resembles modern bone forceps, and has artistically modelled handles and blades which possess strong teeth for gripping.

"An elevator for raising depressed bone is another interesting exhibit. Its presence in the collection would seem to prove that after battle efforts must have been made to treat surgically even the most serious wounds of the skull.

"Another and still more remarkable brain instrument is the drill-bow for operating a skull trephine. This instrument proved a very great puzzle at first, and was supposed to represent some sort of measuring appliance. Research, however, has shown that it is a bow, which, when fitted in a string, was used to rotate a bone drill or skull trephine—very much as drills and trephines are still, occasionally, rotated. The British Museum possesses the only other specimen of the drill-bow extant; until the discovery at Kolophon was made, the nature of that instrument was not known.

"Far from being a triumph of modern surgery, skull trephining or trepanning is a very ancient manoeuvre. Skulls have been discovered again and again showing trephine openings, and the natives of the South Sea Islands are actually known to practise the operation. In classic times this was not undertaken, as at present, to relieve pressure, but to allow exit to the evil spirit supposed to be troubling an insane or epileptic patient.

"The collection also includes a tenaculum, or sharp hook, similar to those in everyday use, a number of catheters of beautiful workmanship and shaped like modern instruments of the same type, a scoop, or curette, for gynecological and other work (Hippocrates speaks of such an instrument), a cautery for burning wounds, a couple of probes exactly like the modern ones, a couple of spatulae or spoons, a needle-holder, and a bronze box intended, evidently, as an instrument case. In addition there is a slab of Egyptian porphyry for mixing ointments upon, and a well-constructed pair of scales, still in excellent equipoise.

"Some cupping vessels were also discovered. The method of using these was to ignite a piece of dry linen placed inside of them and then apply them to the skin. As the heated air within cooled it contracted and sucked the skin into the neck of the cup."

THE MAGGOT TRAP A POSSIBLE SOLUTION OF THE FLY PROBLEM.

A trap to destroy the maggots of the typhoid or housefly before they develop into winged insects, is a possible solution of the fly problem and one that should interest health officers, sanitarians and others who might make use of it on manure heaps, where this common pest breeds. The Department of Agriculture's scientists in their preliminary experiments with such a trap have succeeded in destroying from 70 to 99% of the maggots in a pile of manure. This method of attack differs from those which have been generally used. Fly poisons have been made to tempt the appetite of the adult fly, or fly-tight receptacles have been used to keep the adult female from laying her eggs in manure. The newer method is based on the knowledge of certain habits of the undeveloped fly maggot.

The maggots of the typhoid fly, it has been discovered, have a habit of migrating from their breeding places into drier portions of the manure heap. This seems a distinct move on their part to permit the adult fly to issue from the refuse in the easiest and quickest manner. The efficiency of the new trap is based on the regularity of this deep-seated habit.

The experiments of the department's entomologists showed that with the trap from 98 to 99% of all the maggots in the manure pile were destroyed, if the manure was kept moist. From comparatively dry manure about 70% were destroyed.

These experiments, as yet, have been tried only on a comparatively small scale. The question immediately arises whether the trap, which appears so successful on a small scale can be adapted to the handling of manure in a practical way on a large scale. Every consideration points to the probability that it can and that it will afford "an additional weapon of great value." However, the final verdict as to the value of the maggot trap must wait upon the solution of certain practical problems. To point out some of these here is to suggest lines for further investigation.

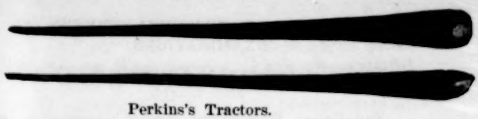
ITALIAN DENTISTS AND DENTISTRY.

THE following item from a recent issue of the New York *Times* describes the present status of dentistry and dentists in Italy.

"With general progress and consequent increase in wealth, the practise of modern dentistry is growing throughout Italy. The United States is looked to there, as in all foreign countries, as the alma mater of this profession. The Italian dentist has supplied himself with the latest and best instruments and appliances. All of them prefer American-made supplies, though, by reason of higher cost, American instruments and appliances are not yet general, but the demand is increasing, as few such instruments and appliances are made in Italy.

"Italy has only one school, the Istituto Stomatologico Italiano, in Milan, where dentistry is taught. The laws now regulating the practise of dentistry in Italy were passed in 1912, and they provide that no one shall be permitted to engage in this profession who has not received a diploma in medicine and surgery. Therefore, to matriculate at this school the appplicant must have graduated in medicine and surgery from one of the recognized universities. As the minister of public instruction is authorized by these enactments to establish departments for the study of dentistry in all schools where medicine is taught, Italy may soon have a number of dental colleges. Under these laws any person who, on March 31, 1912, had been engaged in dentistry in Italy for eight years or more, is permitted to continue in the exercise thereof for one year, but is prohibited from doing so thereafter, unless within this year he passes the prescribed examination in dental pathology, anatomy and physiology.

"There were in all Italy in the year 1906 only 750 dentists. This number increased to 1200 in 1912. At Leghorn, with a population of 100,000 inhabitants, there were only four dentists in 1903; now there are twice that number there.



"Dental inspection and treatment is provided free for the children attending the public schools of some of the larger cities. An examination made in the public schools of Leghorn by a local dentist resulted in a report that sixty per cent. of the attending children needed treatment."

Correspondence.

PERKINS'S TRACTORS.

NEW YORK, May 1, 1914.

Mr. Editor: These metallic tractors gave rise to a medical delusion which prevailed in this country and Europe about a hundred years ago. They were used for the relief of pain and disease by Dr. Elisha Perkins (1745-1799), an eminent physician, president for a long time of the Connecticut Medical Society. They were hammered out of iron and brass, flat on one side and half round on the other, and came in pairs,

Perkins's Tractors.

"the white" and "the yellow." The accompanying photo-engraving shows very nearly their size. It was reported that many cures were effected by drawing them over the affected part, and the inventor believed that he had made an important medical discovery. After his death the treatment was widely advertised, and the tractors were sold in large numbers, the price in London in 1802 being five guineas. They gave rise to the poem, "Terrible Tractoration," and also to a number of books discussing at great length the merits of the new treatment. In 1884 four of them were found in the house of my grandfather at Plymouth, Massachusetts, where he was a minister, early in the last century. They had lain undisturbed for many years in a cupboard, and were tied up with old-fashioned hat pins and hair pins. I kept them several years without knowing their significance till I happened to see a pair framed and carefully preserved in the library of the New York Academy of Medicine. It seems desirable to print a picture of these curios as doubtless specimens are to be found in cupboards and bureau drawers of old houses in this country and England. I am told that those first made were stamped with numbers, and that letters patent to Dr. Perkins, signed by President Washington, are held by descendants of the inventor residing at Springfield, Mass.

Yours truly,

A. B. JUDSON, M.D.

MEDICAL JUDGES.

BOSTON, MASS., May 5, 1914.

Mr. Editor: In the issue of the JOURNAL for April 16 you commented on a bill that was before the Senate at Albany, "providing for a medical judge in each county whose duty it shall be to attend any trial at which medical evidence is taken concerning the sanity of a party to an action and give medical advice to court and jury. The medical judge's instructions are to have the same weight as those of a trial judge."

It would seem that such a measure would make for expediency and justice in the trial of cases involving the question of the sanity of the transgressor. The physician-judge, by limiting the technicalities that are so often injected into such trials, would increase the advantageousness of the alienists' expert testimony. The result would be a speedy crystalization of the facts concerning the case followed by a just and humane disposition of same.

Medical judges might sit not only in the above type of case in which there is a question as to whether or no the criminal is feigning insanity to evade due punishment, but he might also sit at commitment cases. At the latter cases his services might be of especial value in detecting cases not suitable for commitment.

I do not wish it inferred that I mean to insinuate that our judges are not men of high moral integrity and of alert and vigilant mentalities, but I do contend that the physician (other requirements such as maturity, age, etc., being equal, of course) by virtue of the pertinent training and experience he has received, is inherently and eminently qualified to do justice to this sort of work.

To be sure, this would be a new field for the physician, but there is not any reason why he would not be superbly successful in it.

Very respectfully and faithfully yours,

GAETANO PRAINO, M.D.

UNITED STATES CIVIL-SERVICE EXAMINATIONS.

TECHNICAL ASSISTANT IN PHARMACOLOGY (MALE).

June 1, 1914.

The United States Civil Service Commission announces an open competitive examination for technical assistant in pharmacology for men only. From the register of eligibles resulting from this examination certification will be made to fill vacancies in this position in the Division of Pharmacology, Hygienic Laboratory, Public-Health Service, at salaries ranging from $1800 to $2000 a year, and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion.

The duties of this position will consist of research work in pharmacology, including original investigations in the physiological assay of drugs and of the action of drugs by means of the electro-cardiograph.

Applicants should have a reading knowledge of French and German.

An educational training, including a degree of Doctor of Medicine from an institution of recognized standing, and at least two years' subsequent experience in experimental pharmacology and physiology, such experience to have included the study, by means of experimental methods, of the action of drugs, are prerequisites for consideration for this position.

Applicants must have reached their twenty-fifth but not their fortieth birth day on the date of the examination.

Persons who meet the requirements and desire this examination should at once apply for Form 304 and special form to the United States Civil Service Commission, Washington, D. C.; the Secretary of the United States Civil Service Board, Post Office, Boston, Mass.; Philadelphia, Pa.; Atlanta, Ga.; Cincinnati, Ohio; Chicago, Ill.; St. Paul, Minn.; Seattle, Wash.; San Francisco, Cal.; Customhouse, New York N. Y.; New Orleans, La.; Honolulu, Hawaii; Old Customhouse, St. Louis, Mo.; or to the Chairman of the Porto Rican Civil Service Commission, San Juan, P. R. No application will be accepted unless properly executed, including the medical certificate, and filed with the Commission at Washington, with the material required, prior to the hour of closing business on June 1, 1914. In applying for this examination the exact title as given at the head of this announcement should be used.

DENTAL INTERNE (MALE).

June 3, 1914.

The United States Civil Service Commission announces an open competitive examination for dental interne, for men only, on June 3, 1914. From the register of eligibles resulting from this examination certification will be made to fill a vacancy in this position, at $600 per annum, with maintenance, in the Government Hospital for the Insane, Washington, D. C., and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion.

The department states that it reserves the right to terminate the appointment at the expiration of one year of service if it is deemed advisable to do so.

In addition to many interesting cases presented, the dental interne is given an excellent opportunity for study and for doing experimental and research work in the pathological, histological, and other laboratories of the institution.

Applicants are required to be graduates or senior students or regularly incorporated dental colleges, and applications will not be accepted from persons who have been graduates for more than two years. The names of senior students will not be certified for appointment until they have furnished proof of actual graduation.

Applicants must be unmarried.

Persons who meet the requirements and desire this examinations should at once apply for Form 1312 to the United States Civil Service Commission, Washington, D. C. No application will be accepted unless properly executed, including the medical certificate, and filed with the Commission at Washington in time to arrange for the examination at the place selected by the applicant. In applying for this examination the exact title given at the head of this announcement should be used.

NOTICES.

AMERICAN SOCIETY FOR THE CONTROL OF CANCER.

Under the auspices of the Boston City Federation, the American Society for the Control of Cancer will conduct a meeting at Huntington Hall, 491 Boylston Street, on Tuesday, May 19, at 3 p. m.

PROGRAM OF MEETING.

Subject: "The Prevention and Control of Cancer." Addresses by:

Mr. F. L. Hoffman, Newark, N. J., Statistician, Prudential Life Insurance Co., "Prevalence and Increase of Cancer in the United States."

Dr. F. S. Simpson, Pittsburgh, Pa., Alleghany General Hospital, "Work and Purposes of the A. S. C. C."

Dr. J. C. Warren, Boston, President of the Harvard Cancer Commission, "Education of the Public on the Cancer Problem."

SYMPOSIUM.

What the Public should know about Cancer in order to avoid its suffering and mortality:

About "Cancer of the Digestive Organs," Dr. S. J. Mixter, Surgeon, Massachusetts General Hospital.

About "Cancer of the Breast," Dr. W. W. Chipman, Surgeon, Royal Victoria Hospital, Montreal.

About "Uterine Cancer," Dr. H. C. Taylor, Surgeon to the Roosevelt Hospital, N. Y., Chairman, Publicity Commission, A. S. C. C.

About "External Cancer," Dr. David Cheever, Surgeon to the Peter Bent Brigham Hospital.

Closing remarkes by the Rev. George A. Gordon.

RECENT DEATHS.

DR. NEWTON F. CURTIS, who died recently at Milton, Mass., was born in Camden, Me., on July 13, 1849. He graduated from Bowdoin College in 1871, and in 1873 from the New York College of Physicians and Surgeons. He immediately began the practise of his profession at White Plains, N. Y. He had lived at Milton since his retirement in 1910. He was a member of several New York Medical societies. He is survived by one daughter and by one son.

DR. PAUL EHRHARDT, of New York, died on April 30, in his 59th year. He was a native of Pennsylvania, and was graduated from the medical department of New York University in 1878. He practised first at Lauden, Iowa, and in 1883 removed to New York.

DR. EUGENE F. PEARCE, of Brooklyn, N. Y., died on April 30, in his 56th year. He received his academic education at New York University, and was graduated from the Long Island Medical College in 1883.

DR. JOHN MACCONNELL, who died recently in Boston, was born at Belfast, Ireland, in 1839. After graduating from Trinity College Medical School, Dublin, he migrated to Boston in 1868. In 1872 he became superintendent of the local smallpox hospital, and later was transferred to the board of health, where he became its first vital statistician.

FEEBLE-MINDEDNESS AS A LEADING SOCIAL PROBLEM.*

By E. E. Southard, M.D., Boston,

Director, Psychopathic Hospital, Boston; Pathologist, State Board of Insanity, Massachusetts; and Bullard Professor of Neuropathology, Harvard Medical School, Boston, Mass.

Should I declare that the problem of the feeble-minded is the largest single practical problem before Massachusetts at the present day, you might be disposed to wonder how practical a person I might be. Is not insanity a larger problem? Or alcoholism? Or syphilis? Or even that narrow circle of diseases dealt with by boards of health, the so-called public health problem? Are not crime, graft, undesirable immigration, illiteracy larger problems? What also of the high cost of living, classes *versus* masses, anarchistic socialism? On still broader planes, one might pause to contemplate the lowering of moral standards, and the decay of religious thinking by the people at large. What chance has the problem of the feeble-minded with such problems as these and countless other problems of civilization?

Perhaps I may justify my declaration, which smacks at first of such superlatives as are sometimes fed to legislative committees, as follows: By "problem" I do not mean an unsolvable problem or a set of conditions working out in *saecula saeculorum*, so that, if there be a problem, it would require philosophical or even divine wisdom to solve. By problem I mean something concrete, finite, practical, a set of conditions whose dimensions and quality are known or can shortly be known, for us in Massachusetts as well as for the angels in the sky. A problem, as I somewhat narrowly use the term, means a problem for solution, a problem that can by human means be solved.

Insanity is a larger problem financially, perhaps, than feeble-mindedness. Within ten years or much less time, we shall know the comparative costs of the insane and the feeble-minded. Yet the facts of mental disease are of infinite complication beside those of feeble-mindedness. The problems, so-called, of paranoia, of Booth, of Guiteau, of Czolgosz, of Schrank; or the problems of genius and psychopathic states, of Mohammed say, or of Rousseau, or of Nietzsche, or of Roosevelt,—these problems are not to my mind as yet problems; the would-be solvers of such problems cannot agree even on definitions. We may put away as many psychopaths as we like here in Massachusetts; is any one so skilful as to catch up them all as they pass? So much of the insanity-field as, in the present state of knowledge, can be regarded as a problem is either solved or is on the road to solution shortly. Shortly we may say perhaps, as I was told in the Berlin district in Prussia, "There are beds enough for the insane; the numerical question is settled, at least for the present output of insane about Berlin." We may, it is true, need more psychopathic hospitals, that is, clearing-houses where the diagnosis can be made days earlier than by former methods and to which patients will be brought so that diagnoses can be officially made months earlier than was formerly the case. We may need sanatoria for mental cases, where people who can pay less than $25.00 a week can be safely brought through their early attacks or through conditions falling short of frank insanity. We may need extensive developments of the colony system for the able-bodied insane and of the family-care system for the harmless insane. Yet most, if not all, of these developments are officially under way and in a state to be appreciated and furthered by the interested public, that is, by the social workers. That is to say, as I see it, what the state can do has been done or is about to be done for the insane; we must now wait for science to make for us new practical issues, real problems, such as seem to be coming in the science of the nervous system at about the rate of one in five years.

You will readily see how I should logically dispose of such so-called problems as those of alcoholism and syphilis. Much of each so-called problem is in no condition for practical effort. We can readily calculate the cost and human effects of alcohol and syphilis. We lightly say they are preventive problems. But who has anything concrete and universally convincing about ways to head off the desire to get drunk and the desire for sexual intercourse when that desire has no justification in morals, art, or even pride? To be sure, the alcohol problem is being approached on its reform aspect, and a clearing-house for all alcoholics with a follow-up system for each case has been dreamed of. Yet the psychological problems lodging therein, as well as those surrounding the sex instinct, are in no condition for public propaganda. Preaching against alcohol and sex indulgence is in my experience often pointless. Drunkards, prostitutes, and their associates may present a dire "condition"; they do not promise to yield a "theory" for many years.

Those partial aspects, then, of the huge complexes of conditions which I have mentioned (alcoholism, syphilis, tuberculosis, and typhoid fever, in the public health field, crime, etc.), which have been really and seriously reduced to the simplicity of "problems" are either tolerably well met or do not in my opinion meas-

* Psychopathic Hospital Contribution, 1914.4, being contributions from the Psychopathic Hospital, Boston, No. 38. The previous contribution 1914.3 was by Dr. H. R. Stedman, entitled "The Art of Companionship in Mental Nursing," published in the Boston Med. and Surg. Jour., Vol. clxx, No. 18, April 30, 1914, p. 673. The present communication was read at Haverhill before the Annual Massachusetts Conference on Charities and Correction, in October, 1912.

ure up to the size of the feeble-mindedness problem. So far as insanity is understood, Massachusetts has met or is about to meet the problem well. The same may be said of alcoholism and of crime in general. The psychology of the alcoholic, the sex offender, the criminal, hardly presents the aspect of a problem. It is the same with precisely that portion of insanity that interests us most. Was Mohammed an insane epileptic? Doubtless the Mohammedans are the better for their belief in God which Mohammed drove in. Was Rousseau a madman? With more like him, education would present more real problems. Was *Also Sprach Zarathustra* indirectly an outcome of syphilis? With more Nietzsches, much more good German would have been written A melodramatic thrill runs down our backs when somebody says Roosevelt is crazy, but only on the erroneous hypothesis that "crazy" means he should be locked up. If crazy means genius, and really means it, if we knew enough about genius to say that it is a form of insanity and really think so, then to call Roosevelt crazy would be campaign ammunition for Roosevelt.

As a fact, the psychology of alcoholism, of the sexes, of crime, of genius, of many borderland and complex types of insanity is so far virtually devoid of problems in the perhaps narrowly social and practical sense in which I have applied the term.

The problem of the feeble-minded is a practical one for us for many reasons.

In the first place, our social sense concerning feeble-mindedness has been aroused. We look sharply at each other nowadays to see if we are not in some degree feeble-minded. To be a moron or high grade feeble-minded person is getting to be as common as having a Darwinian tubercle on one's ear. We look suspiciously at persons of other races and religions to see if they be not feeble-minded. Our friends even are thought often to be contracting imbecile marriages. I often excuse myself for social errors by considering that such and such factors have been left out of my composition. Even officials are interrupted in their conservative tasks by eager social workers who want something done with this or that person who ten years ago would never have been termed—with safety—an imbecile.

With this arousal of our social sense concerning the true range of feeble-mindeness has come a certain pessimism. Are we not all a little weak as well as a little queer? Are we not all fit subjects in some sense for commitment to a school for the feeble-minded, if not for commitment to a hospital for the insane? Where shall the line be drawn?

As a matter of fact, our laws concerning the commitment of the feeble-minded as concerning the commitment of the insane are effective enough. As with the insane, so with the feeble-minded, the present problems no longer touch those legal processes involving judges. Little or no doubt attaches to cases suitable for commitment by the court.

More doubt attaches to the proper fate of those considered by some as suitable, by others as not suitable, for admission to institutions without court process. The line of distinction roughly runs between custodial cases adjudged by a court suitable for commitment and what might be termed educational cases which the institution sees fit to receive as mentally deficient.

The ground for optimism here is the popularization of the Binet-Simon tests which, combined with common sense and some medical knowledge, make it possible for a comparatively inexperienced examiner to do in a short time what formerly depended on the teacher's trial and error. The intellectual educability within well-defined limits can now be safely declared for a given case by scores of workers,—scores as compared with a handful twenty years ago.

But intellect is not all. Will tests and tests for capacity to do things remain to be placed on the same plane with the Binet-Simon intellectual tests? Here is where inexperience in the examiner counts and where the off-hand Binet-Simon diagnosis of the psychologist and social worker meets shipwreck at the institution. Aside, however, from the complex and high-grade cases, where will disorder and criminal tendencies enter, the popularization of the new tests has rendered much more easily possible the winnowing of cases for the new beds which the legislature has granted and will surely continue to grant.

Psychopathic hospitals and out-patient departments, which naturally go therewith—it is a question whether every great district hospital for the insane should not support an out-patient department for these and other appropriate cases—will aid extensively in the solution of the problem along the lines of the out-patient department conducted at Waverley for many years. Already, before its formal opening, the out-patient department of the Psychopathic Hospital in Boston had had a large number of such cases brought for diagnosis—a majority, in fact, of all out-patient cases there.

What is the size of the problem? A conservative estimate in 1911 stood at 6,700. A special study now being made by Dr. William Noyes*

* A sample of Dr. Wm. Noyes' work done under the State Board of Insanity has been published in the Fourteenth Annual Report of that Board, being Document No. 63. A summary is as follows:

KNOWN FEEBLE-MINDED IN MASSACHUSETTS.

By present census:		
Males		2640
Females		2367
		5007
Reported by overseers of the poor		245
Total not in institutions		5252
In School for the Feeble-minded (at Waltham)	1497	
In Wrentham School	418	
	1915	
In State hospitals and asylums	672	
Total in institutions		2587
Total in State in feeble-minded status		7839

under the Board of Insanity, taking account of undoubted cases (so as not to cloud the issue with mental and criminalistic cases), has not approached this number as yet, but over a third of the number have been found almost at the outset by carefully guarded inquiries.

The result of such inquiries is at first sight pessimistic. I get the impression that the majority of people regard feeble-mindedness as a necessary affliction of society, classing feeble-mindedness in this respect with poverty and crime.

I have to observe in this direction that, whereas a certain minimum of feeble-mindedness may be constantly found in different societies, there is much to be said that the problem is in large part a preventive one.

I have myself of late spent much time upon the geographical distribution of degeneracy and defectiveness in Massachusetts and have to report a surprising *chiaroscuro* in that distribution. I cannot as yet assign definite values to the correlations being studied. It seems, however, that the movement of insanity and other forms of mental defect corresponds rather with the movement of physical disease than with that of crime and pauperism. The mental problems as a whole appear to be rather medical matters, to be attacked by a philosophy of prevention. The crime-pauperism complex statistically appears rather more an economic matter. There is probably a middle ground where feeble-mindedness especially approaches criminalism and where a change of economic status might be the reverse of an aid to society. Mayhap all these tentative conclusions of statistical study will be overthrown.

I should suppose, however, that statistics as a whole and the special kind of analytical statistics known as eugenics has gone far enough to prove that the social philosophy of prevention has wide scope.

To be sure, studies in Massachusetts seem to show that many a case of feeble-mindedness is due in some sense to encephalitis, congenital syphilis, or meningitis in the childhood of the case, so that the particular warnings of eugenics have not a universal scope. Still the practical problems remain preventive. It is probable that there is an interplay of hereditary and somatic factors at work in many cases, not yet sufficiently studied.

What the eugenics workers have abundantly demonstrated is the old law of assortative mating. Part of the statistical *chiaroscuro*, which shows far more defectives in some places than in others is doubtless due to such assortative mating, combined with the propinquity entailed by barriers.

Society, therefore, can readily find out statistically where to work; it can start such preventive mechanisms at work as the somewhat threadbare experiences of public health workers afford; it can thwart assortative mating of the unfit; it can educate; it can transplant; it has means of determining which persons belong undoubtedly in institutions (whatever doubt may rage in criminalistic cases); it knows where to study further; it sees a sufficiently large, if not the largest single, practical problem before it.

I will sum up and conclude as follows:—

1. The status of the feeble-minded in Massachusetts is such as to offer a large and immediate practical problem.

2. The availability of Binet-Simon and other intellectual tests makes desirable the establishment of numerous dispensary centers for preliminary diagnosis, so that cases suitable for well-tried educational methods in our state schools may be winowed out.

3. The criminalistic group has been singled out, hardly so far as a problem of the present, but as a problem of the future, dependent for solution on psychological data not yet available.

4. Estimates of the numerical size of the problem are available, and a promising preliminary survey is being made by the Board of Insanity.

5. Social sense of the importance of the problem has been aroused, though not, it may be hoped, to the point of impatience with the degree of progress humanly possible.

6. The interest of specialists in children's diseases has also been aroused, and the eventual results of certain children's diseases are being shown in the concrete case.

7. Workers in eugenics are being enlisted to study the hereditary factor in some of these so-called "acquired" cases, and, it is hoped, will solve the problem of the interplay of heredity and somatic factors in the pathology of feeble-mindedness.

8. Statistical inquiries seem to justify the idea of a *chiaroscuro* of distribution, which means that society is not just generally degenerating and that the places to begin preventive work can be chosen scientifically.

9. Statistics tend to indicate that the problem is rather a medical than an economic one, or perhaps better, more medical than economic, standing a bit one side perhaps from crime, some part of which is economic.

10. The interplay of hereditary and somatic factors promises to show lines of prevention both eugenic and environmental.

11. We can educate communities in eugenics and we can conceivably transplant, by a proper family-care system, feeble-minded persons from neighborhoods where they would unite with others of their kind to regions where they would either not marry or would marry normal persons, thus diluting the strain (feeble-minded males are probably less dangerous in the community than feeble-minded females, which latter should be segregated by preference in institutions).

12. Socialism of the Fourier-Marx type will have to reckon with this problem; it would not appear that communism has any ready solution

for the problem of those who, being feeble-minded, are by nature neither free nor equal. On the other hand, some form of socialism of the St. Simon type, or what may be termed state socialism, is the most practicable form to cope with this problem. Indeed the practical solution of these problems of feeble-mindedness and allied defects is fast leading us to something of the sort, whether we choose to call it socialism or not. Yet how many would-be socialists face the congenital or acquired inequalities of men with frankness and clear understanding?

UNDER WHAT CONDITIONS IS THE DIAGNOSIS OF "TUBERCULOSIS" IN CHILDREN JUSTIFIED?*

BY JOHN B. HAWES, 2ND, M.D., BOSTON.

THE question raised in the title of this paper is an important and pertinent one. There are many who believe that the theory of childhood infection is being carried too far. However opinions may differ as to this, everyone will agree that the diagnosis and treatment of tuberculosis in childhood is one of the most important, if not the most important problem, not only in tuberculosis and its prevention, but in the entire field of preventive medicine. The children of today are the men and women of tomorrow; the weak and sickly children of this decade are the consumptives of the next, whether or not scientists still wrangle over the problem of the path and the exact time of infection. It is, therefore, urgently necessary that some definite standard be adopted and recognized by every one as to the exact signs and symptoms, or group of signs and symptoms on which it is just to make such a diagnosis. Of course I do not refer in this paper to children with advanced pulmonary tuberculosis, with or without a positive sputum.

It is indeed a step which demands the utmost consideration to stamp a young child as tuberculous and to cast on him and on the family the stigma, however slight this may be, that the name carries with it. Tuberculous infection is one thing,—tuberculous disease is another. Statistics, based on careful pathological investigation, as well as on the results of tuberculin tests, offer clear proof that a large proportion of children, 60% to 90%, according to different observers, are infected with tuberculosis by the time the fifteenth year is reached. This does not mean tuberculous disease, or what we generally term "clinical tuberculosis." Many of these children, indeed the great majority, are perfectly well and without symptoms. How to recognize and do justice to the comparatively small proportion in whom the disease is active and is causing symptoms, what should be their treatment, and how radical steps should be taken in reporting and segregating these patients are most important and ever-present problems.

In Boston, and I presume elsewhere, there is at the present time a great diversity of opinion among doctors at the various clinics as to diagnosis and treatment of this class of children. It is perfectly possible for an anxious mother to take her small boy of ten to one large clinic and be told that he has consumption and must (and is made to) leave school; at the earliest opportunity she takes him to another clinic where the boy is again examined by equally skillful and conscientious physicians, who tell her that her boy has a cold, but certainly has not "consumption." Much relieved, but still anxious, she takes him to a third clinic, where an x-ray of the chest is taken. This discloses a few "bronchial glands and peribronchial thickening with a slight haziness at the right apex." The x-ray expert reports his diagnosis as "Bronchial Glands. Ph?" Exactly what this means may be, but usually is not, explained to the mother, and in any event, as can be readily imagined, fails to relieve her worry over her boy. And so the case drags on, the mother naturally (and quite properly) refusing to allow her son to be sent to a sanatorium or hospital for consumptives, and the physicians at one, at least, of the three clinics visited, still firm in the belief that here is a case of tuberculosis which needs radical treatment.

The following case is a striking example of this state of affairs:—

L. R., a little Armenian girl of 7, living in the thickly settled Armenian quarter, was sent to me for examination from one of the settlement houses of that district. There was a doubtful history of exposure from a grandmother, who had recently died of tuberculosis, and from a brother in whom such a diagnosis had been made, but later not substantiated. The exposure from the grandmother was also eliminated as a factor, to my satisfaction at least. The child had been examined on the morning of the day she was sent to me at a local tuberculosis clinic by two leading authorities in tuberculosis in this city, and pronounced tuberculous on the following evidence. Cough at night, morning temperature, night sweats, and history of exposure,—the last somewhat doubtful, as shown above. Examination at this clinic showed "a definite active process at the right apex, with a limited right basal expansion and well-marked signs of bronchial glands." The mother was told that her child had consumption, and that she must leave school. My examination in the afternoon showed a strong, well-developed and nourished, healthy-looking child. The tonsils were very much enlarged,—sufficiently so to account for any cough or fever which she might have at night or any other time. In the lungs aside from very slightly increased signs at the right apex, I could find nothing abnormal in any way. No râles were heard at any time.

* Read before the New England Pediatric Society, March 27, 1914.

The d'Espine sign was negative. There were no glands. One tooth was carious. I definitely committed myself in writing as being unable to find any evidence of active or clinical tuberculosis in this case, and that I could see no reason why she should not go to school.

A few days later the child was taken to the children's department of another large general hospital, where she was carefully examined by several leading pediatricians, and where I again went over her. Here, in the morning, she had a slight temperature of 99.2°. The lungs were pronounced negative. The d'Espine sign at this visit was negative. A careful skin tuberculin test, done at two separate occasions, was entirely negative each time. An x-ray was taken which was inconclusive, while a later one showed a few enlarged bronchial glands. At this later visit also the child had a cold, and the d'Espine sign became a positive one until the cold subsided, when it returned to normal limits.

The case was not considered one of clinical tuculosis.

Later the child was taken to another dispensary and pronounced normal. The mother, naturally enough, has refused to take her to any more doctors, but is still greatly worried over the question as to whether or not her child has consumption.

This case represents an unfortunate state of affairs. Others similar to this are not uncommon, and are bound to increase as time goes on, unless some definite standard is reached and agreed upon by all. The physicians who saw this patient, whether they regarded her as a case of tuberculosis or not, were sincere in their desire to do what each thought was right; treatment advised was practically the same at the different clinics visited, except that one group of doctors thought that the child's condition warranted the use of the term "tuberculosis," while the other group did not. The two negative von Pirquet reactions in a child of seven are the only features which those who took the more radical stand must find it hard to satisfactorily explain.*

Everyone will agree that the diagnosis of early tuberculosis in children (advanced pulmonary disease offering no difficulties in diagnosis) must be based on:

(*a*) Bad family history or a history of exposure to tuberculosis.

(*b*) Constitutional signs and symptoms, such as fever, rapid pulse, loss of weight and strength, malnutrition, debility, undue fatigue, anemia, frequent protracted "colds," etc.

(*c*) Local signs and symptoms referred to the lungs, such as cough, often paroxysmal, dry, throaty or even brassy, usually without sputum, hoarseness, unequal pupils, slight substernal dullness with high-pitched intense expiration and whispered voice at the right apex, intense bronchial whispered voice over the spine lower than the third or fourth dorsal vertebrae (d'Espine's sign) and rarely paravertebral interscapular dullness.

(*d*) Evidence of enlarged bronchial glands as shown by the x-ray.

(*e*) A positive tuberculin reaction.

Any child who has constitutional and local symptoms, a positive tuberculin test and confirmatory x-ray evidence, should quite justly be considered as a case of active clinical tuberculosis and be so designated and treated. This is easy enough. The great difficulty lies in the fact that "type" cases are rare, and that in 99% of such children the physician must base his diagnosis and treatment on much less than the above-mentioned symptom complex; he must "size up" and accord their value to the symptoms as they present, balancing in his mind what is lacking here against what is present elsewhere, and finally, he must base his decision on the picture he has so formed. His decision in each case should answer the following questions:

(*a*) Has the child tuberculosis?

(*b*) If so, is tuberculosis the cause of the present symptoms?

(*c*) Is the child a danger to the community?

(*d*) Does he need radical, aggressive treatment in a sanatorium, hospital or other institution for consumptive children?

(*e*) Should he be definitely considered as a case of tuberculosis, reported as such, and his parents or relatives informed of this fact?

(*f*) If not, how can he be kept under supervision and control, and should he be removed from school?

(*g*) If he is taken out of school, what do you offer in its place?

(*h*) If he has not tuberculosis, what is the matter with him, and what are you going to do about it?

What, then, is the relative value of the various points mentioned above, on which the diagnosis must rest? The first, a bad family history or exposure to tuberculosis, is an important factor, if present, but one whose absence need not interfere with a positive diagnosis. While it can be said that for all practical purposes, tuberculosis is not inherited, there is no doubt but that weak constitutions and a lessened resistance to tuberculosis may be and often are inherited. In regard to exposure to tuberculosis, the weight to be given this point depends on the length and intimacy of such exposure. These points should be carefully investigated in every case.

Next in order come the constitutional signs and symptoms. In my opinion, a diagnosis of early clinical tuberculosis in childhood is rarely justifiable, unless such constitutional signs and symptoms are present. Without these, except in very occasional instances, no matter what the x-ray may show, and what the signs in the lungs may indicate, I doubt if it is safe or just to stamp the case one of consumption. On the other hand, I have many times made such diag-

* It is interesting to note that a recent von Pirquet test gave a positive reaction. This may or may not mean that the patient was sensitized by the two former ones.—J. B. H.

noses and occasionally sent children to a sanatorium on constitutional signs alone. There is no field of evidence which better repays careful study than this.

Third in the symptom-complex, I have placed signs and symptoms referred to the lungs. Cough and sputum speak for themselves, and have many causes other than tuberculosis. Marked dullness, râles, etc., are easy enough to find, and require no special skill. The detection of finer shades of dullness, or rather diminished resonance, resistance under the finger, the significance of harsh or puerile breathing, prolonged high-pitched expiration, bronchial whispered voice, substernal and paravertebral dullness, require long experience, constant daily practice with such cases, and the greatest of skill to interpret properly. At present much weight is placed on a positive d'Espine sign. When we analyze what this sign really means, we find that it simply suggests that something is present which transmits the whispered voice and breath sounds from the trachea and larger bronchi through to the dorsal vertebrae at a lower level than is usually the case in normal healthy children. It has been taken for granted that this "something" is usually enlarged bronchial lymph nodes, and it has been further taken for granted that these enlarged lymph nodes are necessarily tuberculous, and further still, that they must be the cause of the child's symptoms. All these hypotheses are interesting if true. I do not think that we yet fully understand just what this phenomenon really does mean. It has been found present in perfectly normal individuals a sufficient number of times to show that, like a tuberculin reaction, while it may mean infection, does not always mean disease; again, it has been found present following various acute diseases, especially measles, often enough to show that it does not always mean tuberculosis. I am strongly of the opinion that further investigation must be made before we can attach much significance to a positive d'Espine sign alone as pointing to a tuberculous infection.

Coming to x-ray evidence, here again we are dealing with something which taken alone is not of great value, but which in conjunction with other features may be of grave significance. It must be remembered at all times that the x-ray picture is one of lights and shadows; that such evidence is dumb, and cannot tell us whether the shadows of the glands we see in the picture mean tuberculosis or not, and, if the former, whether the infection is old or recent, active or latent. Whenever possible the x-ray should be interpreted by an expert and by one who recognizes the limitations of his specialty. Such men do exist, but they are rare.

Finally, what does the tuberculin test offer us in such cases? To me the answer is clear and definite. A negative skin tuberculin test (the only one which should be used in children), in the absence of factors which might cause a negative reaction, if carefully performed and confirmed by a subsequent negative reaction, is as good evidence as there is that tuberculosis can be ruled out. A positive test is not so conclusive, but, like the x-ray, is only a small bit of confirmatory evidence to be taken in conjunction with other features of the case.

In conclusion, then, in answering the question asked in the title, "Under what conditions is the diagnosis of 'tuberculosis' in childhood justified?" I would state my opinion as follows:

1. Let it be clearly understood that by the term "tuberculosis" I mean clinical tuberculous disease which presents a definite picture and which requires definite treatment.

2. In the absence of advanced tuberculosis or a recent infection with some acute disease which might cause a negative reaction, a diagnosis of tuberculosis is rarely justified unless there is a positive skin tuberculin reaction.

3. Constitutional signs and symptoms are usually present and require careful study and investigation. If such symptoms are absent, a definite diagnosis is unwise, although this should not interfere with placing the child under proper treatment.

4. Signs referred to the chest and lungs are of interest and value, if present; if absent, their absence should not preclude a definite diagnosis. If present without constitutional disturbance, look out for chronic influenza and pneumococcus infections.

5. Positive x-ray evidence is of value in conjunction with other evidence. Diagnoses based on the x-ray alone are apt to be wrong, and are unjust to the patient.

THE CAUSES AND THEIR RELATION TO THE TREATMENT OF LATERAL CURVATURE OF THE SPINE.

BY Z. B. ADAMS, M.D., BOSTON.

MANY will remember the work on numerical variations of the spine done by Dr. Max Böhm. He made the statement that the upper surface of the sacralizing vertebra might be tipped and thus cause scoliosis. This may rarely be true. Some three years ago in checking up this work of Dr. Böhm the conclusion was reached that so far as the cause of scoliosis is concerned, lesions of the articular processes were of far greater importance than asymmetrical sacralization.

The x-rays of any clinic show that asymmetrical sacralization is of frequent occurrence in cases radiographed for pain in the back, or loin, etc., where no scoliosis existed. The Dwight collection of spines bears this out for it contains many examples of asymmetrical sacralization, but few of scoliosis. In the few with scoliosis, a lesion of an articular process is present and the transverse processes are normal. There is one

spine, however, which has scoliosis and one broad transverse process, but there is in that spine an absence of the left posterior centre of ossification, of the first sacral segment, which seems the cause of the scoliosis, rather than the broad transverse process.

There are a few pertinent facts to be noted regarding the spine and the base on which it rests.

The column of centra and intervetebral discs obeys the laws of physics for flexible rods. The motions are somewhat limited in certain directions by the shape of the vertebral bodies. By the attachment of ribs and posterior columns *i.e.* the columns of articular processes, the motions of this flexible anterior column are still further limited; they not only govern the motions, but in extension their articular facets are in close contact and they share in the function of weight-bearing. The support of the column is then tripedal. In moderate flexion their surfaces are separated and motion is most free.

The usual ossification of a vertebra is from three primary centres, one for the centrum and one for each lateral mass. In a certain number of individuals the fifth lumbar vertebra is laid down by five centres of ossification instead of three, the posterior lateral mass being divided into two parts. One part forms the pedical, transverse and superior articular process and the other part the inferior articular process, lamina and one-half the spinous process. Sir William Turner has found that in five per cent. of all subjects the posterior part fails to fuse with the anterior part of the lateral mass.

The facet on the upper surface of the sacrum on which the spine rests, faces downward and forward, and in the average female has an inclination downward from the horizontal of forty degrees, and in many individuals this inclination is much greater. The under surface of the fifth lumbar vertebra faces downward and backward, hence, by a forward movement of this body on one side, that is, a rotation of one surface on the other, a lateral tilting of the base occurs. At forty-five degrees of inclination, a movement forward of one-fourth of an inch gives a drop of one-fourth of an inch.

The only bony obstacles to this one-sided spondylolisthesis are the articular process on the top of the sacrum and the inferior articular process of the fifth lumbar vertebra, which are not attached to the vertebra in one out of every twenty subjects. Nowhere are bony anomalies more frequent than in the low lumbar spine and in the sacrum.

The ligamentous supports are the anterior and posterior common ligaments, the intervertebral disc, the ilio lumbar and lumbo-sacral, the interspinous and superspinous, the capsular and subflavel ligaments.

When there is an overgrowth, underdevelopment or deformity of the articular processes, one of the legs of the tripod of support of the spine becomes longer or shorter or unstable. We then have a condition analogous to a camera on a tripod, with one short, long or loose leg.

From an analysis of the twenty-two cases in the scoliotic clinic, of which careful x-rays, many of them stereoscopic, have been taken and interpreted, the results are as follows:—

They are not 22 selected cases which show interesting x-ray lesions, but are all the cases of which we have thus far been able to get good x-rays.

The following list, consisting of four boys and eighteen girls, comprises 2 dorsal cases, 4 between the fourth and fifth lumbar, 14 lumbo-sacral, 1 sacral and 1 infantile.

Deformed third and fourth dorsal vertebra (Bell).

Slipping of seventh on eighth dorsal vertebra (Thomas Judge).

Deformity of right inferior articular process, fourth lumbar (McBride, Case I).

Distortion of right superior articular process, fifth lumbar (Pearson, Parmenter, Connors, broad wing).

Faulty fusion of left inferior articular process of fifth lumbar (Cate, Tuttle, Oakley, White, Gordon).

Faulty fusion of left pedicle with body of fifth lumbar (Morrison).

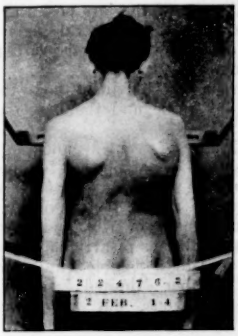
Spina bifida of first sacral segment, sacral articular processes asymmetrical (Guillette, Moore, Kelley, Shapiro, Neilly).

Overgrowth of right superior articular process of sacrum (Swartz).

Absence of neural arches throughout sacrum, its articular processes diminutive (Callahan).

Failure of first posterior segments of sacrum, first sacral centrum deformed (Briggs, Case 2). Faulty fusion of second and third sacral segment on left (K. Judge).

Infantile paralysis, no deformities (Hadgi).



Treatment. The relation of these findings to treatment are as follows:—

From the time of Hippocrates, and perhaps before, various racks, ladders and frames have been used in an effort to reduce or correct the deformities of scoliosis. The deformities often are made worse, or if temporarily corrected they recur. The lateral deviation has been improved in some cases at the expense of an increase of the rotation. Many times the scoliosis is attacked with no regard to the cause of the deformity.

The flexed position, as employed by Drs. Forbes and Abbott, is an undeniable advance, it relaxes the spine with the articular processes separated, thus allowing the freest possible motion. In no other respect are their methods similar. Abbott pulls with the old brute force, in the same direction which has been found in the past, when the spine was locked in extension, would increase the rotation. Forbes, with a thoroughly scientific method based upon a careful research into the physiology of the human spine and the spine of a scoliotic, rotates his case in

CASE II. Briggs.

CASE I. Upper Spine.

CASE II. Upper Spine.

CASE I. Lower Spine.

CASE I. Albino McBride, age 14. July 17, 1913. (First visit O. P. D.)

Curve noticed in April, 1913, by school physical training teacher. Bad posture not noticed before this. Diagnosis: *Scoliosis*, right lower dorsal; left lumbar. Right inferior articular process of fourth lumbar is underveloped.

CASE II. Lower Spine.

CASE II. Ernest Briggs, age 17. August 21, 1913. (First visit O. P. D.)

Complaint: back and chest. Duration: four years. Cause: ? fall.

Present symptoms: pain on lifting. Diagnosis *Scoliosis*.

"Four years ago fell about 30 feet, striking on his side and back and apparently not hurting himself. About three years later he began to notice that he was getting humpbacked and began to have pain in his back. Pain began a short time before deformity was noticed. The pain is only present when he lifts or bends forward."

"Examination shows very well marked degree of scoliosis."

The pelvis is not rotated for the spines of the ischii show evenly. The lower sacrum is but slightly rotated. The neural arches are imperfect throughout the sacrum and the first sacral segment is imperfect and rotated to the left, and its articular processes unevenly distributed from the middle line. Fifth lumbar vertebra rotated to left and tip forward and to the left.

exactly the opposite direction from Abbott, and all other operators. The two methods are diametrically opposed to one another, hence cannot be combined. Strangely enough, either method may correct, and overcorrect in certain cases. In certain cases one method is better than the other. Can we not say that in certain cases relapse will occur and in certain other cases that neither method will correct?

The x-ray findings show that some of these cases cannot be corrected by any method until a bony obstacle is removed surgically. Some of them if they are corrected will certainly relapse unless the defective articular processes are locked together.

Where one side of the fifth lumbar vertebra has slipped forward it must be fastened back in place or it will again slip forward. In the cases where there is a double rotation, the fifth lumbar vertebra rotated to the right, the fourth rotated to the left, the condition cannot possibly be corrected by any method of lateral pulling or rotation.

In cases where there is faulty fusion of the neuro-central suture the fifth lumbar body must be surgically pinned to the sacrum. There is no harm in sacralizing the fifth lumbar body.

Many of the cases due to deformity of the sacrum may be inoperable and best treated by a supporting corset to transmit part of the weight of the body trunk to the iliac crests.

Another fact brought to mind is the danger of treating some of these cases by head suspension, which increases the forward inclination of the pelvis, hence the tendency of the fifth lumbar body to slide forward on the sacrum.

Where the defect is in the articular process of the sacrum or fifth lumbar, these children should be taught to sit with a rounded lower back and stand in the flat-backed position, for this will keep the sacrum under the spine.

CONCLUSIONS.

1. A careful x-ray study in each case is indispensable before treatment.
2. Fourteen of the twenty-two cases in the clinic show a congenital lesion at the lumbosacral junction.

The fact that the age (ten to fourteen) when the anterior lumbar curve becomes constant, is the age when scoliosis develops in a large number of cases is interesting. At this age the weight of the upper trunk is increasing most rapidly and the epiphyses of the iliac crest have not appeared.

The vertebral sacral angle varies widely, but is great in females.

The increased tipping throws greater strain (both downward and forward) on the articular processes, and as the angle of inclination increases the horizontal thrust becomes more vertical and the strains tend to unite. Hence, when these processes are defective scoliosis develops.

3. Many of the cases should be operated on either before correction is attempted or after correction is obtained.
4. A knowledge of the character of the lesion allows a prognosis.
5. This knowledge explains some of the many failures of the past.

It is obvious that in this paper some of the true causes of scoliosis have not been mentioned, but from an inspection of the cases in our clinic attention has been drawn to some of the very frequent causes hitherto overlooked.

NITROGENOUS METABOLISM IN A CASE OF CHRONIC MYELOGENOUS LEUKAEMIA.

By Harry W. Goodall, M.D., Boston,

Assistant in Biological Chemistry, Harvard Medical School; Associate in Medicine, Peter Bent Brigham Hospital; Physician to Boston Dispensary.

In any condition associated either with a considerable increase in the number of leucocytes in the blood or with the destruction of large numbers of leucocytes, such as occurs in Leukaemia, it would be expected that such a change might be indicated by the excretion of urinary nitrogen and more especially by the uric acid nitrogen, in as much as leucocytes are bodies rich in nucleins.

From a review of the rather extensive literature of the subject, it is to be concluded that during the ordinary course of the disease the total urinary nitrogen, as a rule, correspond closely to the protein of the diet and the excretion of uric acid varies only within normal limits. During periods of rapid leucocyte formation or more especially during periods of rapid leucocyte destruction the change may be indicated by the nitrogen output but this is by no means the rule. When such a change does occur it is especially indicated by the increased output of uric acid. No definite relationship, however is found to exist between the number of leucocytes and the quantity of uric acid excreted.

Instances are recorded in which periods of marked leucocyte destruction are accompanied by a diminished or normal excretion of uric acid as well as an increased excretion. Even the rapid dissolution of leucocytes following x-ray exposure may not influence the urinary nitrogen. These varying results have been explained in part by the supposition that there is a retention of some of the intermediary bodies for the purpose of forming new leucocytes and in part by the supposition that the destruction of nuclein is carried beyond the stage of uric acid. In a large measure, however, the variations are to be explained by the shortness of

the period of observation and the failure of the observer accurately to determine the food intake.

In the following case special attention was given to the food intake. The "starch and cream" diet employed by Folin in studying the urine of normal individuals was selected since it is practically free from protein, and fulfills the caloric requirements. At the same time it permits of comparison with normal protein metabolism. The case is of special interest inasmuch as the patient was passing through a period of rapid leucocyte dissolution during the time she was under observation.†

Briefly, the case is that of a Jewish woman, 32 years of age, with a typical myelogenous leukemia which had existed three and a half years previous to this study. For two months, the time previous to and including the period of this observation, she was given Coley toxins nearly every day.

On June 7 (see table below) she was given the "starch and cream" diet for a period of seven days. Previous to this there had been no change in the leucocyte count, but during the period of observation there was a pronounced and rapid fall. It is probable that this fall was entirely independent of the diet, since a second case of leukemia placed under exactly the same conditions failed to show any decrease in the number of leucocytes. Unfortunately the results of the second case are valueless, owing to mistakes in collecting the urine.

Date.	Leucocyte count.	Vol. urine.	Total N.	Uric acid.	Uric acid N.	Per cent uric acid N.
May 31	161,600					
June 7		1815 c.c.	9.9 gm.	0.72 gm.	0.24 gm.	2.5%
June 8		2055	6.2	0.65	0.22	3.5%
June 9	29,800	2676	3.1	0.99	0.33	10.6%
June 10	18,450	1920	7.3	0.74	0.25	3.4%
June 11	14,700	1790	6.1	0.32	0.11	1.8%
June 12		1690	5.9	0.68	0.23	3.9%
June 13	9,550	1500	7.1	0.78	0.26	3.6%
Total			45.6 gm.	4.88 gm.	1.64 gm.	
Daily average			6.5	0.69	0.23—	3.6%
Normal average			5.2	0.33	0.11—	2.1%

The methods employed in making the determinations are those described by Folin.

Subsequent History. Toxins were continued for one month after these observations were made, at the end of which period the leucocytes counts reached a minimum of 3,300. After the omission of the toxins the leucocytes began to increase and reached 45,000. The patient developed a membranous stomatitis and broncho-pneumonia and died in about ten weeks after the end of the period of observation.

In comparing the average daily excretions with the normal there can be no doubt as to a considerable increase in the output of total urinary nitrogen and of uric acid. This increase is more clearly seen if we compare the total excretion of the last six days, the first day being omitted because of its close dependence upon the protein in the diet of the day previous, with four of Folin's normal urine at a corresponding period.

	Total N.	Uric Acid N.
Leukemia case	35.7 gm.	1.40 gm.
Normal person	32.9 gm.	0.70 gm.
Dr. H. B. H.	32.3 gm.	0.59 gm.
Dr. E. A. S.	24.2 gm.	0.56 gm.
Dr. Aug. H.	30.1 gm.	0.82 gm.

Analysis of the table brings out two points of special interest; first, that the daily excretion of uric acid N. shows a wide range of variation, 0.11 gm. to 0.33 gm. without any constant relation to the total nitrogen, and secondly that the day (June 9) when the largest quantity of uric acid was excreted the minimum quantity of total nitrogen was excreted. This suggests the possibility of some error, especially so inasmuch as the urinary nitrogen does not normally sink to this low level with this diet as early as the third day, but constant results were obtained with repeated determinations. It is interesting to note, in connection with the increased nitrogenous metabolism, that the daily quantity of urine excreted was approximately a little in excess of the quantity excreted by normal persons on this diet, and that on the particular day in which the disturbed relation between the uric acid nitrogen and the total nitrogen was the greatest an excessive quantity of urine was passed.

An inference from these observations relative to the metabolism during rapid leucocyte destruction would favor the hypothesis that the destruction can be carried beyond the uric acid stage.

Such a supposition would explain the marked variations which are here shown. Retention for the purpose of new leucocyte formation, while possible, seem improbable in view of the fact that the white count continued to fall and that no increased was noted within four weeks after this period of observation.

† I am indebted to Dr. Ralph C. Larrabee for the privilege of undertaking the study and for the leucocyte counts herein tabulated.

AURAL VERTIGO.*

By D. Harold Walker, M.D., Boston.

The subject of aural vertigo was first brought to my attention by coming in contact with a remarkable family, eleven members of which, during four generations, were affected with vertigo of the apoplectic type. This series I reported in the Transactions of the American Otological Society in 1910. Since that time I have observed a number of similar cases, and recently I had the opportunity of attempting the relief of the distressing symptoms by operation, upon a case kindly referred to me by Dr. Clarence J. Blake.

Aural vertigo is a symptom common to a number of affections such as the more or less transitory vertigo, due to toxaemia, to gastric, or to ocular causes; but at this time I wish to discuss the form of vertigo which is often called Pseudo-Meniere's disease. It is an affection that occurs most commonly in persons of middle age; persons usually healthy in every other respect, the attacks occurring at almost any time, often with no regard as to whether the patient is active or at rest.

That the labyrinth is a closed cavity is the opinion of all observers. Although there are the aquaeductus vestibuli and the aquaeductus cochlae, they are not patent for the free passage of fluid, according to the researches of Schwalbe and Schonemann. The aquaeductus vestibuli contains the ductus endolymphaticus, which ends in the saccus endolymphaticus, an organ which has long been overlooked, yet a constant in all animals where hearing is a sense. One cannot here enter into a description of the important part it plays in the lower animals, nor its prominence in the development of the human ear.

Suffice to say that it is always present, and from the experience of Kummel, its preservation is necessary for hearing.

When one appreciates the extreme sensitiveness of the equilibrium, which must be maintained in the labyrinth to enable the perception of delicate sound waves, it is reasonable to believe that, if there were an intimate relation between the cranial cavity and the labyrinth, the constantly varying intracranial pressure would destroy that equilibrium. The experiments of Lafitte-Dupont showed that variations in intracranial pressure cause similar changes in arterial pressure. Also, the yet unpublished work of Dr. Ayer of this city shows the enormous variations, which may occur in intracranial pressue, and that the withdrawal of varying amounts of cerebrospinal fluid does not, necessarily, cause vertigo or deafness.

It is a recognized fact that there exists in the organism, in the normal state, an energy or a principle which determines and preserves the amount of fluid in serous cavities. This is true whether it be the pericardial, the pleural or the cranial cavity, the eye and probably the labyrinth. If the venae Galeni in the brain becomes closed, hydrocephalus results. If the canal of Schlemn is closed, glaucoma is the result. Is it not possible that pathological changes may occur in the labyrinth, causing an increase in pressure, and vertigo be the result?

It is generally admitted that true apoplectic vertigo is caused by increased labyrinthine pressure, and this belief is justified by the fact that what relief has been obtained has been through agencies which cause either a lymphatic or a circulatory depletion, such as pilocarpine, adrenalin, purgatives, lumbar puncture, the use of setons or, by the surgical destruction of the labyrinth. Again the theory is strengthened by the results of the removal of the stapes, with a transient relief of the attacks of vertigo, and the recurrence of attacks after the foramen ovale has become closed.

Patients affected with this type of vertigo nearly always have diminished hearing, to a greater or less degree. This is true without respect to age. In the cases which have come to my attention, there is little objective evidence of middle ear change, so that the conclusion drawn is that there is a degree of osseous change, which in the first place would destroy the extrinsic mechanism for the control of labyrinthine pressure, as shown by Blake and Wales. Secondly, is there any reason that the process be limited to that portion of the labyrinthine capsule? Could not that osseous change involve the region of the aquaeductus vestibuli, causing a cessation of any function the saccus endolymphaticus may have, acting as an intrinsic organ of equilibrium? Also, could not that same change affect the lumen of the aquaeductus cochlae and of the aquaeductus vestibuli, resulting not only in impeded drainage, but possibly in a passive congestion, by retarding the venus flow? If the foregoing suggest a possible hypothesis, it would explain the reason for the gradual increase of pressure, until a maximum is reached where relief is obtained by a sudden decrease in tension, due to the forcing of fluid through the lymph spaces in the aquaeductus cochlae or a rupture of some part of the membranous labyrinth. The sudden lowering of the labyrinthine pressure would occasion the apoplectic attack of vertigo.

Attacks would recur when the anatomical conditions were reestablished, and after a period of time depending upon the rapidity of internal secretion.

The case I wish to present is that of a man about thirty-five years of age. Previous history of any affection of importance is negative. Habits good. There has been a gradual decrease in hearing, with tinnitus, for several years. The first attack of vertigo occurred eight years ago; since then they

* Read before the International Otological Congress, Boston, August, 1912. Received for publication March 20, 1914.

have varied in severity and are often accompanied with nausea and vomiting. No noticeable change in the tinnitus after an attack. The usual therapeutic measures were of no avail, and lumbar puncture, with the withdrawal of from 15 to 20 c.c. of fluid was performed six times without any relief. I may add that there were no unpleasant after-effects due to the withdrawal of the fluid. The hearing is as follows:

RINNE TEST.

RIGHT.	LEFT.	
25″ a.c.	20″ a.c.	35″ Blake fork used, 256 v. d.
10″ b.c.	8″ b.c.	12″

$\left.\begin{matrix}35'' \\ \hline 12''\end{matrix}\right\}$ = Normal.

d. v. 128 c low limit c.
d. v. 8128 c high limit c monochord, same for a.c. and b.c.

Whisper heard in the right ear at a distance of 6 feet, and a low spoken voice heard in the left ear at a distance of 1 foot. Blood pressure about 135 mm. of Hg. Spinal pressure 30 mm. Because of extreme vertigo, vestibular tests were not performed. It was desired to preserve the hearing, if possible, and it was decided not to do the complete labyrinth operation as performed by Lake, but to destroy the ampullae of the horizontal and the posterior semi-circular canals, without destroying the cochlea. The usual antrum operation was performed, exposing the external horizontal canal. The cortex was partially sclerosed and very vascular. Whether the vascularity was indicative of an osseous change is questionable. The antrum was enlarged sufficiently to allow access to the vestibule without doing a tympanomastoid exenteration. The right semi-circular canal was entered with a dental drill, with absolutely no flow of perilymph as a result.

The vestibule was gently curetted through the anterior limb of the horizontal canal, and the lower limb of the posterior semi-circular canal was followed into the vestibule with a curved probe. The wound healed by first intention, and the patient was discharged from the hospital in about ten days. There was no tympanic reaction from the operation. There was marked lateral nystagmus towards the affected ear. I have not seen the patient recently, but he states in a letter that he had returned to work, that the vertigo had disappeared, but that the tinnitus persists, and that he staggers when he walks. As the operation was performed but eight weeks ago, it is probable that compensation has not yet been established.

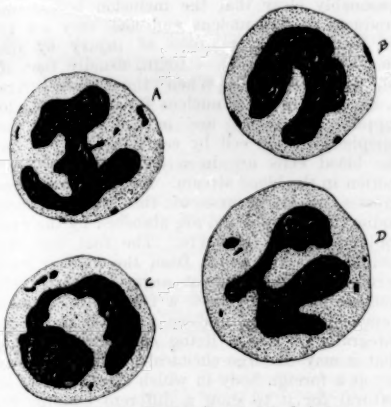
The fact that true aural vertigo causes such great prostration and is such a great inconvenience to the sufferer makes it essential that we do all that is possible to alleviate the symptoms or cure the affection. In mild cases, where there is a more or less constant feeling of disturbed equilibrium and fear of impending attacks, depletion in the various ways in which it has been practised, as reported in literature, is recommended. Randall proposed in 1902 the use of small doses of adrenalin, as a capillary depressent, and his results have been very favorable.

Lumbar puncture, as first performed by Babinski, the French observers as reported by Molard, and by Blake and Putnam, should be tried. There is no doubt but that in certain cases alleviation and even complete relief has been effected by lumbar puncture, with the withdrawal of the fluid, and if done fairly soon after an attack, the labyrinthine pressure might be sufficiently reduced to give immunity from future attacks for a long time.

In just what way lumbar puncture may effect the intra-labyrinthine pressure is not known. In the above case it was performed six times with no effect upon the symptoms. The fact that there was absolutely no flow of the perilymph at the time of operation is in accordance with the theory of the closure of the aquaeducti. Dr. Ayer in the work already mentioned, performed lumbar puncture upon a series of about twenty cases and in one case only was there a complaint of temporary deafness and slight vertigo. The symptom most common to all was more or less headache. It is reasonable to suppose that withdrawal of any amount of fluid from the cranial cavity, in normal persons, would be immediately reformed. It is possible, that where beneficial results are obtained, they are probably due to a permanent lowering of the hypertension of the cerebro-spinal fluid.

In most severe forms of the disease, destruction of the labyrinth, as first performed by Milligan and later by Lake, seems to be justifiable.

REPORT ON LEUCOCYTIC INCLUSION BODIES.*



BY LEWIS WEBB HILL, M.D., BOSTON,

Medical Interne, Massachusetts General Hospital, Boston.

DÖHLE'S leucocytic inclusion bodies are small coccus- or bacillus-shaped bodies occurring in the polynuclear leucocytes of the blood in a number of diseases, especially in scarlet fever, and were first described by him in November, 1911. Since then, many articles have been written about these bodies so that another one would perhaps seem superfluous, but it may be of some value to report 100 cases studied at the South Department, Boston City Hospital. There will be no attempt made to give an extensive review of the literature as this has already been done in previous publications.

Döhlé himself first considered these bodies to be fragments of a disintegrated spirochaete which had been ingested by the polynuclear blood cell and called it the spirochaete of scarlet fever, believing it to be specific. This has, however, been discredited. Kretschmer, in 1912, examined 85 cases, 15 scarlet fever and 70 con-

* Read before the New England Pediatric Society, March 27, 1914.

Four Leucocytes Showing Characteristic Inclusions.
A shows prolongation of nucleus.
B shows most characteristic position of inclusions at periphery of cell.
C and *D* show variations in morphology of inclusions.

trols consisting of various diseases, and found the inclusions present in all the scarlet fever cases and in only four of the controls, those positive being two cases of diphtheria, one of tuberculosis and one of pneumonia. He was not able to reproduce the bodies in the blood of animals after injection with scarlet fever material.

Nicoll and Williams examined 51 cases of scarlet fever and 25 controls of diphtheria, erysipelas, pneumonia, tonsillitis and German measles, 45 of the scarlet fever being positive and only 3 of the others positive. These were one case of pneumonia, one of erysipelas and one of measles. Nicoll later reported a new series of 115 scarlet fever cases and found positive results in all but 16, all except 3 of these negative cases having been ill for over 7 days. 8 cases of erysipelas were all positive, as well as 7 cases of sepsis, most of them of puerperal origin.

Ahmed believes that the inclusions have a definite relation to the amount of fever and is of the opinion that they are fragments of the nucleus. Kolmer examined 214 cases of scarlet fever and found bodies present in nearly all of the early cases and in a few of the late cases, one as late as the 44th day. He also found them in 13 out of 50 cases of diphtheria examined in the first few days of the infection. Of 30 cases of serum sickness, developing a rash, none showed inclusions. Kolmer also examined bloods from a number of other diseases and concludes that the inclusion bodies bear a definite relation to the streptococcus toxin and that they are present in 94% of all scarlet fever cases during the first three days. He believes that they represent a degenerative process in the cell cytoplasm. He could not reproduce them in rabbits by the injection of scarlet fever material.

Granger and Pole had 191 cases of scarlet fever, 37 of measles, 27 of diphtheria, 24 of tonsillitis, 20 of pertussis, and 20 of serum rash, besides a number of other diseases. They found bodies present in 17 of the measles cases, in 27 of the diphtheria and in 14 of the tonsillitis cases. All of the scarlet fever cases examined before the fourth day were positive, but all except one of the pertussis cases were negative and all of the cases of serum sickness were negative. They conclude that the absence of inclusion bodies during the first four days of the sickness practically excludes scarlet fever.

Lippmann and Hofschmidt reached practically the same conclusions as the other authors cited concerning the occurrence of the bodies, but they believe them to be a product of excessive cell destruction in the body, which has been taken up by the polynuclear leucocytes. They consider that there is a parallelism between urobilinogen excretion in scarlet fever and the occurrence of the inclusion bodies, both being indices of cell destruction due to toxemia and fever. Bongartz regards them as products of the cell nucleus, which have been broken off by the action of bacteria, not specifying any particular group.

Schippers and de Lange were able to reproduce inclusion bodies in the blood of a dog after the injection of a streptococcus culture. They say, "The inclusion bodies are certainly not derived from the nucleus because they have different staining properties. For example, they stain red with methyl green and pyronin while the nucleus stains green."

Cummins believes that they are to be found in practically all febrile diseases, in chronic pyogenic conditions of afebrile character, in severe injuries without febrile disturbance, and in some normal individuals. He was not able to reproduce them in laboratory animals and believes that a nuclear origin is probable. Glomset found inclusions in the blood of normal individuals, 2 to 4% of the polynuclear leucocytes containing them. After the blood had been shaken vigorously with citrate solution, the percentage of leucocytes containing inclusions rose to 15 to 20%. He regards them as detached portions of the nucleus and says that in many cases the nuclei of the polynuclear leucocytes show partly detached fragments, similar in outline to the free bodies.

All of the scarlet fever bloods to be reported in this communication were obtained at the South Department of the Boston City Hospital, at the City Hospital proper and at the Massachusetts General Hospital. Four stains were used:

1. Granger and Pole's modification of Manson's stain prepared as follows: Methylene blue 1.5 grams; absolute alcohol 10 cc.; 5% solution of phenol in water 100 cc. Methyl alcohol was used as a fixative, it being sufficient to dip the slide into the alcohol, wash with water and immediately stain. This was

a very satisfactory stain. With it the inclusions stain a deep blue, the cell nucleus deep blue and the cell protoplasm a pale homogeneous blue.

2. Pappenheim's pyronin and methyl green (2 parts of pryronin to 4 parts of methyl green in saturated aqueous solution) was also found very satisfactory. This stain makes the prettiest preparations, the inclusions staining bright red and the cell nucleus a greenish blue.

3. Wright's blood stain.

4. 1% aqueous solution of pyronin.

Of these stain 1 and 2 are the most satisfactory.

One hundred bloods were examined as follows:

	Positive.	Negative.	Total.
Scarlet fever	43	29	72
Erysipelas	5	0	5
Pneumonia	4	1	5
Syphilis	0	2	2
Empyema	0	1	1
Secondary anemia	0	1	1
Serum rash	0	1	1
Normal	0	13	13

A case was not called positive unless well-defined and well-marked inclusions of fair size and characteristic appearance were seen in at least two or three leucocytes. Of the 29 negative scarlet fever bloods, all except 6 were after the tenth day. Three of these six were on the second day, one on the fourth and the other two on the eighth and ninth days. Of these six cases it is interesting to note that the temperature was normal and there was only a very scanty rash. All of the three which were negative on the second day were positive when examined again on the third day. Of the positive scarlet fever cases, 25 were before the tenth day and eighteen after it, the latest being on the 45th day.

The inclusions are perfectly definite, small, irregularly-shaped masses which stain homogeneously. Their average length is about one micron. They may be pyriform, ovoid, coccoid or bacilliform in shape. They usually lie at the periphery of the cell and in some cells there may be as many as five or six. The most characteristic ones are of the shape of a rather short, thick bacillus, usually with rounded ends and lie on the periphery of the cell with their long axes parallel to it. In any normal blood, there may be seen small granules which may superficially resemble the inclusions, but a blood should not be called positive unless absolutely characteristic and undoubted forms are seen. I have not been able to find inclusions in normal blood. It has been my experience that the sicker the patient, the higher the temperature and the more abundant the rash, the larger and more abundant are the inclusion bodies. In many of the polynuclear leucocytes may be seen small prolongations of the nucleus, as observed by Glomset; sometimes these are attached to the nucleus only by a very narrow strand and resemble in every particular the free bodies. It seems reasonably clear that the inclusion bodies are products of the nucleus and that they are in the nature of a reaction of injury by the nucleus to the bacterial toxin, usually that of the streptococcus. When these bodies are broken off from the nucleus it is reasonable to suppose that they are moved towards the periphery of the cell by centrifugal force, for the blood cells are in a continuous rotatory motion in the blood stream. As the disease progresses, in the course of time the inclusion bodies disintegrate and are absorbed by the protoplasm of the leucocyte. The fact that the bodies stain differently from the nucleus with certain stains does not argue against their nuclear origin, for once a fragment has been detached from the nucleus, it is no longer an integral part of the living cell. It is possible that it may undergo chemical changes and may act as a foreign body in which case it would be natural for it to show a different staining reaction from that of the nucleus. I was not able to reproduce inclusion bodies in the blood of a guinea-pig by the injection of a mixed culture of staphylococcus and streptococcus taken from the throat of a scarlet fever patient whose blood showed inclusions.

From my own observations and from those of other writers it seems fair to draw the following conclusions:

The inclusion bodies are present in a majority of cases of scarlet fever up to the tenth day; in nearly all cases before the fourth day.

They are not specific for the disease, being found in a number of other infections, most particularly erysipelas, sepsis, pneumonia and tonsillitis. They are more likely to be found in diseases with which the streptococcus is associated.

They have the following diagnostic value: If they are not found in a doubtful case which has a rash and a marked fever, the case is probably not one of scarlet fever. They are never found in cases of serum sickness (uncomplicated.)

They are probably in the nature of a reaction of injury of the cell nuclei, caused by bacterial toxins and are small fragments broken off from the nuclei.

I wish to express my indebtedness to Dr. Edwin H. Place, Physician in Chief of the South Department for permission to use the material in the wards and for his interest throughout the work.

POOR HEALTH IN THE CHILD: SOME DEVELOPMENTAL INFLUENCES AND THEIR IMPORTANCE TO THE ADULT.*

By John Bryant, M.D., Boston.

OUTLINE.

I. Introduction.
II. Developmental influences classified.
  A. Variations in type forms.
    1. Herbivorous.
    2. Intermediate. (Normal human.)
    3. Carnivorous.
  B. Variations common to all types.
    1. Abnormal psersistence of normal fetal structures.
    2. Alterations in development of normal fetal structures.
      a. Arrest of development.
      b. Excessive development.
    3. Absent development and malformations.
  C. Variations in development of the ductless glands.
    1. Metabolic disturbances.
      a. Organic.
      b. Inorganic.
    2. Trauma.
    3. Other causes.
III. Observations on post-mortem material.
  A. Method.
  B. Thorax.
  C. Diaphragm.
  D. Adhesions.
  E. Ptosis.
    1. Stomach.

    3. Kidney.
    4. Liver.
  F. Nutrition.
    1. Intestine, and duodenum.
    2. Biliary system.
    3. Cartilage changes.
      a. Rib.
      b. Knee joint.
  G. Ductless glands.
IV. Clinical observations.
V. Diagnosis.
VI. Treatment.
VII. Conclusions.

I. INTRODUCTION.

What per cent. of ptoses, adhesions, and other abnormalities of the adult are congenital? What proportion of the community suffers from them? What is their influence upon health? What is the proper treatment of these conditions? What is their influence upon the health of the children of the future?

These and other questions are the results of experience with the often unsatisfactory medical and surgical treatment at present applied to a large class of semi-invalid children and adults included under terms such as sickly, congenitally unfit, asthenics, visceroptotics, and neurotics.

The present paper outlines the first steps in a systematic attempt to put some of these questions on a basis which will permit of a satisfactory answer, and is in the nature of a preliminary note on some two years of work, more detailed reports of which will appear later. Much of it is from a period of sixteen months at clinics and post-mortem rooms in Europe; the remainder is more recent, especially certain observations from the children's department of the Massachusetts General Hospital Out-Patient Department, some findings during the new second year course in cross-section anatomy at the Harvard Medical School, and a rather extensive review of the literature, a summary of which may be found in the form of a bibliography which has recently appeared.*

My belief in the importance of the pediatric end of this developmental problem results from post-mortem work upon the adult, for it soon became evident that many of the peculiarities found in adults could also be demonstrated in children, in infants, and often even in the fetus. In such a case, it is obvious that the primary problem lies not in an adult, but in the child or infant in whom this adult has his origin; conversely, it has seemed probable that many an adult could have been spared years of misery and inefficiency, and have had much added to his productive power by adequate attention during his period of growth.

The world is full of people who from the point of view of the efficiency expert are below par; who as hypo-producers and often as hyper-reproducers become to a variable degree a burden upon the resources of others. Having excluded such extraneous causes as alcohol, syphilis, hookworm, and faulty habits, there will remain many cases for whom some other explanation than a neurosis must be found. Of these, many may be traced to demonstrable physical defects. But it is not enough to call the sufferer bilious, or weakminded, or tubercular, or rheumatic; for constitutional differences largely determine the diseases to which the individual is liable. Tuberculosis is a marked example of a disease which thus becomes a symptom by which we may state the developmental type of its victim.

The developmental influences to be discussed may be considered under the following three groups.

II. DEVELOPMENTAL INFLUENCES CLASSIFIED.

A. *Variations in Type Forms.* From a developmental point of view, man, judged by his intestine, belongs between the carnivorous and the herbivorous animals, and is more nearly related to the latter than to the former (Treves). Consequently the race falls into three type groups: (1) the herbivorous, (2) the intermediate, and (3) the carnivorous. It has long been known that type 1 has a wide short body form and a relatively long intestine, and that type 3 has a thin long body form and a relatively short intestine. This relationship between body form

* Read in part at the meeting of the New England Pediatric Society, May 1, 1914.

* *Surg., Gynec. and Obstet.*, May, 1914.

and intestinal length has been traced as far down in the scale of life as the reptiles and the insects (Dreike). Type 2 is of course less sharply defined, being as it is intermediate between the two extremes. More recently Bean has distinguished three groups on the basis of the germ layers, and has not only been able to recognize them by body form and the shape of the ear, but has made a rough classification of the diseases to which each type is subject. Also, and with reason, there have been many reports on the effect of the upright posture upon the viscera, a change which bears hardest upon the long, loose jointed, trumpet eared, carnivorous type of individual, since his loosely adherent viscera, so well adapted to his four-footed manner of life, work at a great disadvantage in his new attitude; and Goldthwait has found that these type differences apply to the shape of the lumbar vertebrae no less than to the other components of body form.

B. *Variations Common to All Types.* In this group belong many variations of the viscera, which may be roughly classified as follows:

(1). Abnormal persistence of normal fetal structures.

(2). Alterations in development of normal fetal structures: (*a*) Arrest of development. (*b*) Excessive development.

(3). Absent development and malformations.

As an example of (1) may be mentioned the persistence of the caudal edge of the ventral mesogastrium, causing constriction of the duodenum, just reported by Harris; (2a) is represented by the undescended cecum or by a common mesentery for the whole intestine, and (2b) by such formations as Lane's kink. Under (3) would come such abnormalities as absence of a segment of intestine, or of the abdominal wall, or the presence of a true megacolon, as recently observed in a stillborn infant at the Harvard Medical School.

C. *Variations in the Development of the Ductless Glands.*

(1). Metabolic disturbances. (*a*) Organic. (*b*) Inorganic.

(2). Trauma.

(3). Other causes.

There is less known about this group than about the other two, but that the effects of varied diets upon the development and activities of the ductless glands is of real importance, with the resultant possibilities of alterations in function of the whole organism, is sufficiently evidenced by reports in the literature.

III. OBSERVATIONS ON POST-MORTEM MATERIAL.

Largely in Group IIB fall my observations on material obtained in Berlin through Prof. Pick at the Friedrichshain Krankenhaus and through Prof. v. Hansemann at the Virchow Krankenhaus during the fall of 1912 and the spring of 1913. Although more than three hundred autopsies were followed during the year in Berlin, Prague, Vienna, Hamburg, and other places, it was difficult to obtain the freedom desired, and even in Berlin various circumstances combined to prevent my obtaining satisfactory records in more than 218 cases. Undertaken as an orientation in the study of ptosis in the adult, the literature was avoided in order that any conclusions might be unprejudiced. Having reached certain conclusions, and having now reviewed the literature, it is hoped that by a study of an additional 300 cases in Europe during the coming six months, some valuable results may be obtained; for though it is doubtful if many new combinations will be recorded in a further series, a total of 500 autopsies should give a sufficient basis for establishing the normal limit of variations in unselected material,—a standard now sadly needed by which to judge findings in small groups of cases.

A. *Method.* To use a metaphor from deep-sea dredging, it seemed probable that from the application to the problem of a mental dragnet, in the form of a record of as many different facts as possible concerning a given case, whether seemingly related or not, there should result some light on the questions of cause and effect within the abdomen. The necessity of such a method of attacking the question is made the more obvious by a review of the literature. One may find nearly all the single facts of interest recorded, but thus far it seems that no one has attempted a correlation of the whole. The material was unselected, including men, women, and children, infants, and feti, from a length of 12 cm. to an age of 89 years, and the following observations are based for the most part on the first hundred of these cases. Notes were found valueless unless written in the interval between the examination of one case and the next, and it was necessary for purposes of comparison to record the observations obtained under 58 different headings. The work was done without interfering with the routine post mortems, the external measurements and observations being made before the autopsy commenced, and the viscera examined *in situ* during the routine examination of the thorax, the intestine being measured after removal from the body. After experience with about 30 cases, the following system was arrived at:

Four sets of cards were used: 1. External measurements, etc.; under this heading were recorded the case number, sex, age, occupation, disease, and height; also two measurements of the thorax, three of the abdomen, two of the diaphragm, the length of the small intestine and of the large intestine, and the condition of the rib cartilage and of the cartilage of the knee-joint. 2. General observations; such as development, nutrition, the amount of external fat, peculiarities of the thorax, abdomen, extremities, heart, lungs, and diaphragm, the presence of icterus, or ascites, the condition of the omentum, and the amount of intra-abdominal fat. 3. General intra-abdominal; as adhesions, presence of gall-stones, and remarks on the gall-bladder, liver,

spleen, pancreas, kidneys, adrenals, and genitalia. 4. Gastro-intestinal; adhesions, apparent length and disposition of the transverse colon, and notes on the condition of the stomach, pylorus, duodenum, ileocecal valve, appendix, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, sigmoid flexure, and rectum. It was not possible to obtain notes under every heading on each case, but even an average of notes under some 28 headings per case has supplied some interesting correlations. The adhesions proved difficult to record, and resulted in a mere note of presence or absence on card 4, while on card 3 a detail was given by means of numbering the organs from 0 to 17; thus in case 73, a man of 87, the figures 0-1-2-3-4-9-11 signify a mass of adhesions, including the liver, peritoneum, omentum, gall-bladder, duodenum, ascending and transverse colon. Case 54, a man of 60, with adhesions numbered 3-4-11, 2-4-11, is interpreted as a band from the gall-bladder across the duodenum to the transverse colon, and a band of omentum across the ascending and transverse colon, thus giving in this case practically the lesion to which Harris recently referred, and a form of Jackson membrane. In case 87, a man of 76, under 3-4-11, 1-7, and 2-13-14, we have three lesions, the band across the duodenum from the gall-bladder to the transverse colon, the appendix bound to the peritoneal wall, and a band of omentum across the descending colon and sigmoid flexure, or more properly speaking, the iliac colon.

B. *Thorax.* In measuring the thorax, two levels, determined by convenience, were used for the purpose of recording variations in the size of the lower thorax. In all newborn infants measured, the circumference at the tip of the eighth rib equaled or exceeded that at the lower border of the sternum; the upper level falls below the breasts of the female, and the lower is at a natural angle of the ribs, below which it is difficult to use even a steel tape with accuracy owing to the rapid decrease in size of the thorax as it merges with the abdomen. One does not often find the lower measure less than the upper until about 5 years of age, after which the narrowed chest increases in frequency, so that in the total of 9 children in which this double measurement was recorded in this first series, only 57% have the full normal infantile type, and in the total of 43 adults one finds the normal in only 33% of males and 37% of females. Thus we see that the full infantile thorax, at least in the working class from which this material is drawn, is slightly more common in the adult woman and the so-called tapering feminine thorax of the artist is rather more common in the grown man; in other words, the male thorax is abnormal in 67% and the female in 64% of these cases. In using these thoracic measurements, it is observed that all complicated calculations are avoided, and that, first, although both measures may be the same, both may be above or below the normal for a given height; second, when the upper measure is normal for a given height, the lower measure is really the more important, since it is a better indicator of internal derangements.

What is the significance of this change in thorax form? Harris, as later discovered, has concluded that nephroptosis in the adult runs parallel with this narrowing lower thorax, and that he can predict the position of the kidney by his measurements. He finds the kidney low in 56% of 126 adult women, and considers the low kidney the result of the narrowed body form. He believes that owing to the lessened capacity of the thorax, attributed by Goldthwait partly to postural depression of the diaphragm, the liver is forced downward, it in turn acting directly to depress the kidney; this is soon sufficiently low so that all further downward pressure acts above the centre of this organ, to force it still further downward, and thus such trauma as coughing tends always to increase the nephroptosis.*

Osler considers nephroptosis four or five times as common in women as in men. If this is so, according to Harris the narrowed chest should be much more frequent in women than in men; but from my figures the narrow chest is even more frequent in men than in women; also, a low liver is not incompatible with a high, firmly fixed, apparently normally placed kidney, and conversely, the kidney may be found low with the liver high. Therefore it would seem unlikely that Harris is wholly correct. Is it not more probable that ptosis is rather a cause than an effect of the narrowed thorax, since the incidence of the narrowed chest in the adult is only 65%, while ptosis may be put at 75%, with adhesions yet higher at 84%, and since this difference in relative frequency is even more striking the younger the child?

The causes of this narrowed chest would seem to me to be multiple, as for instance the limitation of body type, an unusually low attachment of the diaphragm on one or both sides, and intra-abdominal conditions such as ptosis and adhesions, in addition to the usual trauma of life, which include occupations, bad habits, and fatigue.

C. *Diaphragm.* In addition to the usual note on the highest level of the dome of the diaphragm on both sides, a second measurement was possible owing to the routine manner of the thorax examination employed by Prof. Pick. Since the thorax was always opened with a knife by a cut along the junction of rib cartilage and bone, it was possible to observe at what level this incision intersected the diaphragm, in other words, to register its height of attachment in this anterior location. A considerable number (40) of observations gave an average height of attachment on both sides at this point, of the seventh rib, with a variation from the sixth to the eighth, on one or both sides, and it seemed

* As a possible source of error in the clinical determination of nephroptosis in the adult is suggested the presence of the so-called corset lobe of the liver; often these little lobes have been seen which, post-mortem at least, would have seemed to have been in life a not improbable source of confusion to the diagnostician.

that this irregularity had some influence on the shape of the lower thorax.

D. *Adhesions.* Adhesions of some sort were present (including frank peritonitis) in about 86% of 77 adults, and 71% of 20 children; excluding peritonitis cases, adhesions or bands were present in 83% of 46 male and 86% of 27 female adults; in children, adhesions were present in 77% of 9 males, and 50% of 8 females, the youngest child in this group being 1 month and the eldest 16 years old with 50% of them between 1 and 8 years of age. Thus, though the initial rate is 22% higher, the adult male has increased his rate only 6% as against an increase of 36% in the female, and in the end the male has a 3% lower rate of frequency than the female. These figures are, of course, from a small number of cases, but they are suggestive in two directions: the female children average younger than the male, and it may be that part of the percentage difference in children is due to age, but this would not account for the final male ratio. On the other hand, even if the female child ratio were for age equal the male ratio, it would make even more striking the fact that at the age of 16 years this series of 100 cases had acquired 85% of its total supply of adhesions. Unfortunately, I have found no figures with which to compare these.

Morris, in a discussion of the location of adhesions, gives four groups in the following order of frequency: Gall-bladder, cecum and appendix, pelvis, and sigmoid. Robinson, giving a longer list of locations reverses this order, *i.e.* mesosigmoid 82%, pelvis 80%, ceco-appendix 72%, and gall-bladder 68%. My results correspond with those of Morris: In detail, the gall-bladder was involved in 58 cases, the transverse colon in 55, duodenum 39, omentum 31, ascending colon 29, hepatic flexure 23, peritoneum 23, liver 21, appendix 14, right kidney 6, cecum, splenic flexure and desecending colon 4, adnexa 3, sigmoid flexure 2, terminal ileum and rectum 1, small intestine, 0. Frank peritonitis from any cause was excluded from this list, and almost no cases except those of peritonitis had been operated upon. In a word, the upper right quadrant was the most common seat of trouble in the proportion of 140 to 19, which number is for the right lower quadrant.

Two other points of interest in regard to adhesions may be mentioned. First, in those cases in which the appendix seemed normal, the various adhesions were fewer, of a simpler type, less often multiple, and less often situated at the flexures; there were fewer gross changes in the gall-bladder itself, but more gall-stones (*i.e.* 19% of 42 abnormal, vs. 8% out of 24 with normal appendices), and slightly more abnormal knee joints (50% of 6 vs. 40% of 14 normal cases). Second, adhesions were absent in only three cases in a series of 25 adults. In two of these the double thoracic measurement was recorded, and in both the thorax was of the full infantile type with the nutrition good.

E. *Ptosis.* In my consideration of ptosis, the transverse colon was eliminated as being too loosely attached. Four organs were chosen for record,—the stomach, ileo-cecal valve, liver and right kidney. It was found that with slight pressure and a downward sweep of the extended hand from the cardiac toward the pyloric orifice, the lower border of the stomach could be closely approximated to the level obtaining in the upright position; the stomach was then called low if the greater curvature came below the level of the umbilicus, and in addition it was noted when the greater or the lesser curvature of the stomach came to the level of the promontory of the sacrum, about half way from the umbilicus to the pubes. The ileo-cecal valve, taken as a more definite point than the cecum, was considered low when its lower border came below the brim of the true pelvis, and the liver when its lower border came below the costal border. The kidney was considered low or loose when it could be moved freely for more than three or four cm. in a vertical direction.

Under these conditions, ptosis was absent in 10% and general in 22%, while one or more of the organs named were low in 75% of 30 cases. In 40 cases the liver was low in 45%, and in 50 the kidney low in 42%. The stomach and ileo-cecal valve were low in 50% of 63 cases, and in these the greater curvature of the stomach reached the sacral promontory in 27%. In another small series, the position of the stomach was recorded in 17 children and 71 adults as follows:

Children.	No.	% Low.	% to Promontory of the Sacrum.
Male	8	63	0
Female	9	88	44

Adults.	No.	% Low.	% to p. s.	% Lesser Curvature to p. s.
Male	42	74	17	2.38
Female	29	90	53	3.48

In all newborn children examined the stomach itself was above the level of the pylorus. In one adult woman and one adult man, the lesser curvature had reached the promontory of the sacrum. Between these two extremes, it will be seen that dilatation of the stomach, for true ptosis of the cardia and the pylorus is not very frequent, is not only distinctly more common in the female at all ages, but of a decidedly more severe type than in the male. This increased frequency in the female applies no less to the position of the ileo-cecal valve, as shown by the following:

Children.	No.	% Low.	% in Pelvis.
Male	9	22	0
Female	7	86	28

Adults.	No.	% Low.	% in Pelvis.
Male	41	41	0
Female	27	66	25

The extreme per cent. in female children is doubtless due to the small number of cases recorded, yet it goes to show that the low ileo-cecal valve is in the female congenital to a much greater degree than in the male. Smith, in a series of over 1000 infants less than three months of age, found the cecum in the pelvis in 10%, but in this 10% there were 34% males and 66% females; thus he found the condition about 100% more frequent in female than in male infants. There is an obvious discrepancy between my figures and those of Smith, but it is at least in some measure due to age differences. As previously stated, the stomach is always small and high at birth; in the same way, the kidney is always high and firmly fixed at birth, and it seems not improbable that some of these recorded differences are due to developmental adjustments of the peritoneum and mesentery, continuing during the first year or more after birth. In any event, it is certain that prolapse of the ileo-cecal valve is much more common in the female than in the male, and that there is less increase with age. In other words, a low, loose cecum is a female characteristic, and it has been explained by several writers on the basis of a physiologic adaptation for pregnancy.

Appendicitis in my series was no more frequent with than without ptosis, which suggests that in such cases it is less often a primary offender than is commonly supposed. It was also noted that the fulminating cases of appendicitis seemed to occur chiefly in children with particularly good health and general development, who showed no sign of pre-existing adhesions about the appendix or elsewhere in the abdomen. Turning back for a moment to the figures on adhesions, it will be seen that in point of frequency for age, adhesions precede the ptoses in the male, while the reverse is true in the female.

F. *Nutrition.* In the field of developmental adhesions about the intestine, my observations have been in accordance with the work of Eastman, Flint, Gray and Anderson, Harris, Konjetzny, Rjesanoff, and others, and there is one new point to add to the subject of duodenal obstruction. In addition to the cause mentioned by Bloodgood, and Codman, and the adhesions demonstrated by Gray and Anderson, one may not infrequently find on careful examination of the duodeno-jejunal juncture a slight anomaly of the ligament Treitz. Usually this ligament is so arranged that the first portion of the jejunum crosses the vertebral column from right to left before turning downward toward the pelvis; but in the cases in question, due apparently to a slight prolongation of the inferior aspect of this little ligament to the right, the duodenum terminates in a jejunum which may reach part way across the vertebral column, only to turn sharply on itself toward the right, following the direction given it by the anomalous ligament of Treitz. The result is obvious: there is provided in this developmental kink an excellent opportunity for the blocking of the duodenum by moderate pressure from a loaded stomach or other cause.

Dilatation of the duodenum was observed with constriction of the lumen by adhesions in 1 or 17.6% of 6 male, and in 1 or 20% of 5 female children; also in 5 or 8% of 65 adults. In 38 male adults dilatation was present in 16% and dilatation with constriction in 6 or 2.6%. In the female adult, dilatation occurred in 40% of 27 cases with constriction in 18.5%. This is in line with the increased frequency of the other intestinal conditions in the female.

Nutrition is apparently in some degree related to the narrow chest, since it is always good in the cases with a normal thorax and usually bad in proportion to the narrowing of the chest in the other cases, that is, with a decrease of the lower thoracic measure below that of the upper of 1 cm. or more. The position of the diaphragm may also play a part here, for out of 8 cases, it is recorded as low in 7 narrowed cases, and as normal in the only normal case. Thus it is possible that variation in the level of the attachment of the diaphragm may be a predisposing cause to ptosis and poor nutrition as well as to the narrowed chest.

My cases confirm the previous observations of others on the existence of a relatively short length of intestine in the tubercular and the asthenics (or static lymphaticus type), the hyperonto-morphs as Bean would call them. It has also seemed that in the absence of constricting adhesions an added length of intestine for a given body height is an advantage; but that in the presence of adhesions interfering with bowel function, added intestinal length becomes a positive disadvantage in proportion to its excess. Consideration of intestinal length is, however, always subject to the finding of almost 100% difference between maximum and minimum length in any unselected series of cases, thus requiring some care in interpreting results.

In a group of children in whom only three were noted as emaciated, these were the only three recorded as having adhesions about the hepatic flexure; they also had very short intestines, that of a boy of 16, for instance, being shorter than that of a healthy girl of only 8 months of age in the same group. These hepatic adhesions were of the developmental type. Is it not possible that in these cases the adhesion determined the lack of growth of the intestine through impairment of nutrition, and that in turn, nutrition was interfered with by the short intestine, thus establishing a vicious circle which could only be broken by relieving the adhesion?

In view of an equal sex distribution of joint lesions and of the preponderance in these lesions of liver and gall-bladder troubles, the sex distribution of gall-bladder changes may be mentioned. No stones were found in children, but the gall-bladder was noted as thick in two of four males, and all of four females. In adults, the gall-bladder was noted as thick in 50% of 26

males and 20 females, but stones were present in 23% of the males and 35% of the females, an increased frequency of 13% in the latter.

It is perhaps admissible to consider here a little end result evidence, as a side light on bodily function, in the shape of late changes in the cartilage in the ribs and of the knee joint. In 53 adults, the rib cartilage was normal in only 4, or abnormal in 92.5%, with 100% abnormal above 35 years of age. The youngest positive case was an emaciated boy of 16, dying from carbuncle of the lip, with the meninges of his brain afloat in pus. There were the usual calcium deposits above the vessels in the rib cartilage. The oldest normal adults were a thin man of 34, with tuberculosis, and a fat woman of 35 with acute post-abortive peritonitis. Aside from the calcium deposits about the vessels above mentioned, the common early change in the cartilage was an apparent drying and granulation of the whole cartilage substance.

The changes in the knee joint were of the type variously called senile, degenerative (Nichols), or hypertrophic (Painter). Occasionally, a slight hemorrhagic area was observed, but usually the change consisted in erosion or fibrillation of the cartilage, sometimes slight and superficial, and sometimes exposing the bone, allowing the formation of exostoses of varying size. The cartilage looked like the end of a twig which had been pounded with a hammer. Below the surface this cartilage almost invariably contained small millet-seed sized white granules, apparently of calcium. When slight, the cartilage changes always appeared first on the patellar surface, suggesting that the process involved the femoral and tibial surfaces only in the more advanced cases.

The knee joint cases are more interesting than those of the rib cartilage, showing as they do more apparent relationship to derangements of the biliary, respiratory, and circulatory systems. The joints were examined in 35 cases of the series of 100 on which this paper is based. If one joint was positive the other was examined, for both joints were always normal or always affected in more or less degree. Children were negative unless tubercular or otherwise clearly infectious. The youngest positive case was a woman of 21, and the oldest negative case a woman of 76. The sexes were affected equally, with about 62% positive, and 75% positive in 20 cases above 50 years of age. The most frequent age period was between 60 and 65, which included 25% of 33 cases. The following associated conditions were noted:—

Condition.	Knee Joints. Normal. No. of Cases.	%	Abnormal No. of Cases.	%
Adhesions	9	100	24	87
Total liver changes	9	11	23	52
Gall-stones	6	17	6	83
Gall-bladder changes	8	12.5	17	70

In height the positive cases averaged less than the negative, and yet the total intestine measured longer. In other words, the intestine relatively was distinctly longer in the positive cases. It may also be noted that this extra length was in the small intestine, for the large intestine was slightly shorter in the positive cases. Likewise the positive group contained the two extremes in intestinal length.

It will be observed from the above table that chronic degenerative or hypertrophe arthritis is more common in a rather short, somewhat thin type of individual, with a relatively long small intestine and rather short large intestine, a type of intestine likewise proved undesirable as the result of studying the nutrition of a group of young children. The joint case has also a high proportion of biliary troubles, of adhesions of the severer grade or those about the flexures, and of low kidneys. Apparently uncomplicated ptosis and simple adhesions are matters of slight consequence. In addition, the positive case shows more rib cartilage changes and a higher incidence of respiratory and especially of cardio-renal complaints.

G. *Ductless Glands.* Two notes on the suprarenal gland may be of interest. 1. Severe extensive hemorrhages were seen in newborn children at the Virchow Hospital. It is suggested that in a non-fatal degree such suprarenal hemorrhage with consequent glandular tissue destruction may be a factor in the suprarenal deficiency of some adults. 2. In later childhood or adult life, as recently observed at the Harvard Medical School, the right adrenal, especially in proportion to the degree of narrowing of the thoracic outlet with the usual low position of the liver in these cases, is exposed to direct pressure between the firm liver and the much firmer vertebral column. This follows upon the fact that the right adrenal, almost wholly unprotected by fat, even in stout people, lies in a thin strip between these two firmer organs; the left adrenal, on the other hand, more triangular in shape, rests in a protective pad of fat, safe from pressure by any heavy organ.

Questions of diet in the control of the ductless glands, as illustrated by the work of Hunt, Schiotz, and others, are certain to engage increasing attention no less than a study of the effects of the action of the different elements

contained in the various drinking waters. It has, for instance, been noted in examining the records of 40 cretins at the Massachusetts General Hospital O. P. D., children's department, that many cases have developed in children who have been breast fed for unusually long periods of time, *i.e.* from one to two years, and that these children have been habitually constipated from birth, sometimes in extreme degree. In a total material of 231287 cases, cretins occurred with a frequency of about 0.06%. One family history may be quoted.

A short stout healthy-looking intelligent Jewess who at the time of inquiry was engaged in getting a divorce. She was the mother of two cretins, the younger of whom was about five years of age. Both of these children were habitually constipated and both had been breast fed for more than one year. She stated with conviction that the whole cause of her misfortune was her long-continued ever-present sexual hatred of her husband. In view of the action of psychic effects upon secretion of the stomach, it is certainly not impossible that intense sexual aversion may act to depress the function of the ductless glands during pregnancy, and various workers on animals have found that a small thyroid or other gland in the mothers always determines the presence of a small or deficient gland supply in the fetus.

IV. CLINICAL OBSERVATIONS.

On the evidence of some 300 O.P.D. records from the children's department of the Massachusetts General Hospital, is presented the following well-known type of sickly child with which clinics are overrun. Though in one the nervous system, and in another the circulatory or respiratory system may seem the chief offender, the gastro-intestinal tract appears always to be involved if only in as mild a form as constipation or diarrhea, and underneath these more or less superficial manifestations, there seems to run a family resemblance in the form of an ill-adjusted or defective organism. Something is out of tune, off color, and the result is bad. One very constant finding is an excess of soaps and fatty acids in the stools, especially in the group of chronic intestinal indigestion cases. These are usually difficult to treat, always have an excess of certain food components in the stools, usually fat, and on examination the pronounced big belly is in marked contrast to the small chest and extremities.

The composite history of these children reads like the index to a standard system of medicine: there is almost always something going on, but there are certain critical periods. Usually marked gastro-intestinal symptoms appear before the age of two months. The child may then disappear until perhaps at two years of age it returns with glands of the neck and a history of frequent coryza, colds, coughs, and middle ear trouble. Then come adenoids, and tonsils, and by five years of age it is almost sure to have added dental caries and perhaps pyorrhea alveolaris to the list. Meantime, it is likely to have had severe pertussis, bronchitis, furunculosis, eczema, or several of these complaints in addition to the usual exanthems; and in spite of all it continues to live and acquire yet more diseases.

On examination this child is pale and pasty if fat, or if thin, sallow with a yellowish tint to the eyes and the dry skin. The liver is felt 1 to 2 cm. below the costal border, with possibly some tenderness over the gall-bladder. The spleen may be enlarged and some degree of anemia is usually present. A blood examination may show in addition to the anemia a slight leucocytosis, with perhaps a relative increase of lymphocytes. Appetite is capricious, sleep poor, and eneuresis frequent. The stools will show constipation or diarrhea, frequently with a foul acid or sour alkaline character. Tuberculosis is frequently suspected. The extremities are negative unless cold and purple, and the thorax, excepting active processes of the lungs or heart, is negative if not flattened throughout or diminished below. There is a curious absence of abdominal palpatory findings, which is in marked contrast to the habitual constipation or diarrhea, and the usual report is: abdomen flat, negative. This absence of local symptoms has often been reported in the study of chronic adult sufferers presenting positive intra-abdominal Roentgen findings. When one adds to the previous ailments those of the nervous system, from tic to epilepsy, the list becomes truly formidable; but it is surprising to see how many of these diseases can be accumulated by one child before it graduates from the pediatric department; and with a little trouble one may follow some of these sickly children through the intervening years to the operating table at the age of 20 or 30 for some intra-abdominal, usually gastro-intestinal complaint.

Compare for a moment the clinical and post-mortem findings. Which would seem to be the more primary, the widespread pathological intra-abdominal lesions of varying degree common to all ages and both sexes, or the multitudinous often evanescent diseases of the child? A consideration of the preceding paragraphs would seem to indicate that the definite pathological findings may act to interfere with nutrition and bodily function to the extent of producing a marked lessened resistance, and consequent increased susceptibility to the diseases to which these children are always exposed.

V. DIAGNOSIS.

Knowledge which will permit of relieving some of the underlying conditions affecting the health of the sickly child or the semi-invalid adult depends upon an appreciation of the significance of body form in its differing types, and of the characteristic postures assumed by these sufferers no less than upon the accepted laboratory methods. In addition there is presented, in

the form of a simple double thoracic measurement, a new, and it is believed a valuable aid, in the recognition of the probable existence of definite intra-abdominal lesions which might otherwise go unsuspected until the application of better known diagnostic methods.

VI. TREATMENT.

The treatment of these cases is essentially non-surgical, in that though an operation may be imperative for the relief of a constricting adhesion or other definite lesion, any approach to a cure is only reached through weeks and months of pre- and post-operative medical or orthopedic care, during which body form must be altered, posture corrected, and diet regulated to stimulate a natural organo-therapy. Failure with milder methods is, of course, the indication for the use of gland extracts or other more radical attempts at cure, but it is certain that no cases are so hopeless as to be incapable of some measure of improvement. The most important single point of attack is the narrowed lower thorax. If this can be restored to the normal full infantile type, the case will show improvement no matter what the intra-abdominal complications. The second indication is to provide the patient with a natural abdominal bandage, replacing the familiar "clam-belly" by firm and efficient oblique and transverse abdominal muscles which will hold his loose viscera where they belong in the now enlarged upper abdominal cavity. In this connection it may be observed that the rectus is less efficient for the purpose than the muscles just referred to, and becomes still less efficient as a binder in proportion to the increased depth of the thorax. The third point of importance is to provide the patient with back muscles strong enough to maintain the normal shape of the thorax under any and all stresses of life to which he may be subject.

A more complete consideration of diagnosis and treatment is reserved for the future.

VII. CONCLUSIONS.

1. Adhesions, ptoses, and other demonstrable physical defects are of very common occurrence at all ages in both sexes, but the frequency of these defects in the adult is not markedly greater than in the child.

2. It is not improbable that such defects may stand in a causal relation to some at least of the disabilities of the child and the adult.

3. An anomalous ligament of Treitz may be a factor in obstruction of the duodenum.

4. A simple double measurement of the thorax is presented, which is likely to prove an aid in the recognition of certain intra-abdominal abnormalities. This measurement is in a variable degree an indicator of physical efficiency, and is useful after the age of five years.

5. The treatment of developmental defects is primarily non-surgical, and if properly carried out in the child is preventive, in that it will result in creating an adult not only personally more efficient, but one who may entertain the hope of having physically more perfect children.

6. "The problem is comprehensive enough to accept all the assistance it can through gymnastics, bandages, regulation of diet, and habits, and still furnish an abundant per cent. of human wreckage (Lane) for the surgeon to attempt to reclaim" (Schachner).

In closing it is a pleasure to express my indebtedness to Prof. Charles S. Minot and to Dr. Goldthwait for their continued interest and valuable suggestions during the progress of this work.

Reports of Societies.

NEW ENGLAND PEDIATRIC SOCIETY.

THE THIRTIETH MEETING HELD AT THE BOSTON MEDICAL LIBRARY, MARCH 27, 1914.

FRITZ B. TALBOT, M.D., Secretary.

DR. MARSHALL FABYAN read a paper entitled,

BACILLUS OF CONTAGIOUS ABORTION.

ABSTRACT: The present efforts being made for the production of clean milk. As scientific investigation advances other factors of unknown importance appear. Dr. Theobald Smith nearly twenty years ago reported lesions occurring in guinea-pigs inoculated with cow's milk, as due to some unknown cause. The close similarity of these lesions to those produced by tuberculosis in the guinea-pigs, was remarked upon. In 1910 we met with similar lesions in guinea-pigs inoculated from the placentae of aborting cows. After much difficulty an organism was isolated which proved to be identical with the bacillus of contagious abortion discovered by Bang and Stribolt in 1895.

The lesions occurring in guinea-pigs are of extraordinary character, involving the spleen, lymph-nodes, liver, lungs and in fewer instances, the kid-

ney, testes, bones and special organs,—eye. These lesions are composed of tubercles made up of large epithelioid cells, having large poorly staining nuclei, containing little chromatin, and a small amount of protoplasm. Small round cells, giant cells and occasionally leucocytes may be present. The bone lesions occur in about 25% of inoculated animals. These include enlargement of the extremities about the joints, and general enlargement of one or more ribs. The process apparently starts in the marrow and stimulates the bone to an extraordinary proliferation. A diseased rib may be two or three times the size of a normal one. No pain seems to accompany the enlargement.

Isolation of the organism from material: When in small numbers or where probable contamination, best to inoculate guinea-pigs. Pure cultures may be obtained from the spleen of such animals after a period of two or more months. Peculiar cultural conditions required. Partial tension of oxygen. Nowak's method,—utilizing the absorptive power of Bacillus Subtilis in a sealed jar. Successful growth by sealing the culture tube itself. After a few transfers the organism becomes aerobic, a property not lost by further animal inoculation. The peculiarity of growth prevents its detection in the usual methods of enumerating the number of bacteria per cubic centimeter of milk.

Milk is a constant source of supply for further infection among dairy herds. Examination of samples of milk from twelve cows in a prize herd, including two which had recently aborted. The abortion bacillus was found in the milk of one which had aborted two weeks before at the eighth month, and in the milk of another which had dropped a normal calf eleven months previous, and had therefore probably given infected milk continuously for nearly a year. Other investigation has shown that only one teat may be shedding the organism. Macroscopically, the udder may appear entirely normal on section.

Schroeder has stated that 10% of market milk is infected with the abortion bacillus.

Method of testing for the presence of the abortion bacillus or its antibodies in cows: Guinea-pig inoculation, agglutination, complement fixation, and the inoculation of a filtrate similar to tuberculin, called "Abortin." Complement fixation has been tried with human serum with some success. Larson and Sedgwick have recently reported having tested by this method, the sera of a number of women who had aborted. They obtained more positive results to the abortion bacillus than to syphilis. They examined the blood of 425 children and found 73, or 17%, positive to the abortion bacillus. They speak of this 17% as having lesions of the osseous system, and in most of them the clinical diagnosis of tuberculosis and rickets had been made.

Undoubtedly the opportunity for the frequent ingestion of the abortion bacillus by man is fairly well established. The question remains as to whether under certain special conditions, such as pregnancy or lowered resistance, this organism is able to gain entrance and produce pathological lesions.

DISCUSSION.

Dr. Marshall Fabyan: In my conclusions I said it is a question whether this organism is able to gain entrance, and produce pathological lesions. I think both of these points should be considered.

Of our laboratory animals experimented upon, the guinea-pig, rabbit and mouse all showed some pathological changes. We were able to reisolate the bacillus from the rat after nine weeks, from the pigeon after eighteen weeks and from the monkey after a period of thirteen weeks, although in none of these animals were any lesions subsequently observed either macroscopically or microscopically. It, therefore, seems apparent that the bacillus abortus may exist and multiply in the body of certain laboratory animals for weeks without producing evident pathological lesions.

Dr. Lewis W. Hill read a paper entitled,

REPORT ON LEUCOCYTIC INCLUSION BODIES.*

Dr. John B. Hawes, 2nd, read a paper entitled,

UNDER WHAT CONDITIONS IS THE DIAGNOSIS OF "TUBERCULOSIS" IN CHILDREN JUSTIFIED?†

DISCUSSION.

Dr. Cleaveland Floyd: I think this is a very important subject and that we should be very grateful to Dr. Hawes for bringing it up. With regard to this particular case, I think it is always of value to make discussions pointed and definite, and I see no reason why we should not so discuss the case which he has presented tonight. I happen to be one of the men to disagree with Dr. Hawes in this particular case on account of the evidence we gathered, which was as follows: A child, as he says, coming from a poor quarter, with a grandmother who has been sleeping with the child for some weeks or months, who later died with tuberculosis in Tewksbury. The child, according to my point of view, was somewhat under-developed and undernourished. The mother at the first examination denied that the child had night sweats, that the child had a cough or any other sign of the disease, but on urging, she admitted what previously she had denied,—that all these symptoms were present. It seems to me that there was definite evidence of consolidation at the right apex, paravertebral dullness and d'Espine's sign, with faulty expansion on the right side, all of which seemed important evidence of a process going on in that lung. This child's temperature was taken a number of times in the afternoon as well as in the morning and there has always been a temperature, varying from 99 to 99.4° F. With regard to the von Pirquet test, this is a very interesting point. Two tests were done at other clinics and were negative. I did one myself subsequent to these and got a perfectly positive result, the diameter of the inflamed area being 1½ c.c. I do not believe that there was any sensitization of the child as the previously inoculated areas did not show renewed inflammation. A number of German observers believe that we have no right to call a von Pirquet test negative unless we have done the test at least three or four times with a negative result in each. This child has been followed by the Boston Consumptives' Hospital since she was first examined. She has been excluded from school on our diagnosis, has been out of school now for three months, has gained six or seven pounds in weight, looks very much better.

The mother is interested in the child and is now doing something for her. From my point of view that child had tuberculosis of the lungs; I think she

* See page 792.
† See page 784.

also had enlarged bronchial glands. I think the d'Espine sign is not one on which to place too much importance. In a recent study of some hundred cases to demonstrate what signs are met with in the bronchial glands, I have about come to the conclusion that the d'Espine sign is one of minor importance. In regard to the importance of the x-ray, I believe that where the x-ray man who knows something about lungs tells you that the case is a questionable one, you had better put it down as tuberculosis. I have seen a number of men working in this particular field, and their ideas of what constitutes a normal lung and normal glands are very variable. In other words, I do not believe that their standard of normal is a correct one. I agree with Dr. Hawes that the early diagnosis of tuberculosis is one of prime importance. I am sure the child is much better today than she was three months ago.

DR. WALTER C. BAILEY: After looking at this subject from the point of view of adult tuberculosis and realizing the lack of progress that we are making in the cure of pulmonary tuberculosis in adults and seeing the constantly increasing numbers coming to us each year with pulmonary tuberculosis and wondering what is to be done, I got interested in the question of tuberculosis in children and childhood infection, and again in reading and finding a good deal of evidence for the theory that practically all adult tuberculosis is the result of infection in childhood. it therefore becomes a general question, and I wouldn't go into this case excepting for one aspect of it, and that is the contact, —the chances for this child to become infected. Now the grandmother, who had lived with the family, had died, and the hospital report at Tewksbury gave the diagnosis as acute miliary tuberculosis. An uncle has died in Syria within a few years, who lived with this family for a period of four or five years, and during this time had one or two hemorrhages, so that he was an active tuberculous source. The father looks very much as if he had tuberculosis, although after one examination the diagnosis was negative. He had a chronic cough at least, and he looks as if he had tuberculosis. I personally believe from clinical experience that it is impossible for a child to become associated for any length of time in a tenement house with an open case of tuberculosis and not become infected. To back up this statement you have the figures published by the Royal German Board of Health, work done under the leadership of Dr. Weber, and very likely some of you have seen it. He published a series of 171 unselected cases coming to autopsy. In 22.5% of these cases viable tubercle bacilli were recovered. Between the ages of two and three, 38.8% gave viable tubercle bacilli. If you get such a large percentage of cases with viable bacilli in unselected cases, what must you get in selected cases? So it seems that we must look at this thing, not as an individual diagnosis, but as an epidemic disease. We all know that in a typhoid epidemic when one is called to see a person who has a fever, rose spots, enlarged spleen, etc., he does not want to stop and make all the tests, but you would say right off, it is typhoid and take all precautions and make your further tests afterwards. Now I think it is only fair to do the same thing in tuberculosis. It is much more of an epidemic than typhoid, and we are never going to get anywhere in stamping out the disease unless we tackle the child problem. This is my idea and very strong feeling. As regards keeping the children out of school, I think here we have one of the most valuable clubs, because you can talk to the mothers and fathers until you are black in the face about bringing the child to the clinic, etc., but when you take that child out of school, they sit up and take notice, and it will surprise you, I think, to learn that up to two or three years ago, it was impossible to make a diagnosis of tuberculosis in a child at the Boston Consumptives' Hospital unless an active process was found in the lungs,—tubercular râles. Now that has been changed and we are making that diagnosis more frequently,—perhaps we are not hitting the bull's eye every time, although I think we did in this case, but at least we are not going backward and we are not standing still. We are calling attention to these facts. We are working toward keeping these sick children out of school. We are going to raise a rumpus among the parents and we are going to try to establish open-air schools. Although we make mistakes occasionally, the principle is right that we ought to be able to make a diagnosis in children with the signs and symptoms which have been spoken of tonight, especially with a history of contact. I want to say a word or two for the derided d'Espine sign. I believe myself it is a valuable sign if you include not only the increased voice sounds over the dorsal vertebrae, but also along the paravertebral lines. We know we can get enlarged glands from measles and whooping cough, etc., but if enlargement persists for six months or a year and the child is going down hill, I think you are fairly safe in calling it tuberculosis. One word with regard to nomenclature. We never will get anywhere unless we throw out the old teachings and call the disease by its right name. We would have been much farther ahead today if the word tuberculosis had been used years ago instead of scrofula. The same is true of the term physiological apex. These two terms belong in the same waste basket.

DR. W. B. SWIFT: I would like to ask Dr. Bailey if in the cases mentioned, where 28% were found to have viable tubercle bacilli, whether there had been any history of exposure previously in those cases.

DR. BAILEY: (Answering Dr. Swift.) The figures given were from a series of unselected cases. There was no statement made whether or not these children had been exposed to infection.

DR. R. M. SMITH: I would like to say a few words, as I was one of the physicians to examine this child. I am perfectly sure that the technic of the von Pirquet tests that were negative was performed as carefully as could be done, and was the same as was used in other cases which proved to be positive, that is, we had really negative von Pirquet tests. The child is getting better, and I believe that she would have gotten better if the diagnosis of tuberculosis had not been made. The treatment is very much the same as in any case of a child in a poor general condition. I think she has suffered perhaps from being deprived of three months of school. Not too much importance can be attached to the interpretation of x-ray plates. The presence of enlarged bronchial glands does not always necessarily mean that the child has tuberculosis. If we accept this sign as positive evidence, I think we are going one step farther than we are justified. I remember a child who had evidence of enlarged bronchial glands, later proved to exist by autopsy, but on physical examination and x-ray examination

showed no tuberculosis. That child had an acute endocarditis with bronchial glands. I have seen cases of chronic influenzal infection which have been followed for from five to seven years, which showed persistent enlarged bronchial glands. I think the d'Espine sign as an evidence of enlarged bronchial glands is very much worth while, but it does not seem enough to me to justify the diagnosis of tuberculosis. There is one other point about the x-ray. It does not seem to me that a positive x-ray plate is sufficient evidence upon which to base a diagnosis of tuberculosis. I saw a patient today who is interesting in this connection. The child came to us six months ago,—she had been exposed to tubercular infection. We went through all the usual procedures and decided that she did not have tuberculosis although the x-ray interpretation of the plate said she had a tuberculous process in her lungs. She was given the ordinary directions as regards hygiene and food which have not been followed very well. She reported today, six months later. She has gained seven pounds in weight and is in perfect general condition. Three of us examined her today and found her lungs absolutely negative in every way. I think in the end it will really be better if we say very frankly that many of the doubtful cases are not tuberculosis and treat them according to rules of general hygiene. It is not quite fair to say that every suspicious case has tuberculosis, and in the long run we are going to lose the confidence of the community if we continue to make the wrong diagnosis.

Dr. F. B. Talbot: I think the trend of this discussion is very promising for the diagnosis of tuberculosis in the future and I am very glad to see that the men who are dealing with tuberculosis in childhood and infancy believe it plays an important part in adult tuberculosis. I think that more and more diseases of adult life will be found to originate in childhood. The various points about this particular case have been discussed so completely that there is no necessity for my saying any more about it, but the discussion has been entirely about tuberculosis contracted by one person from another, and I would not have us leave here tonight without mentioning the fact that it can be gotten from milk, and I have seen a number of cases where the disease has come from the milk taken by young children, and think that this is a very important factor in tuberculosis in children under four years, in fact as important as tuberculosis caused by personal contact.

Dr. H. I. Bowditch: I would like to say one thing in regard to the d'Espine sign which may be of interest to you. About five years ago I began marking charts of patients at the out-patient department of the Boston Consumptives Hospital, with especial relation to d'Espine's sign in childhood. Since then I have with very few exceptions found that when that sign (as I make it) was strongly positive and remained present, that tuberculosis did not exist. The child usually showed some sign of pulmonary tuberculosis later and the diagnosis became positive. Of course this sign varies under different hands. What one man calls positive another may say is negative.

I think when we have an agreed on nomenclature of what these signs and symptoms mean in a child that we will be much farther on the road than we are at present. I should like to ask Dr. Smith what the treatment would have been in the case under discussion if it had not been diagnosed as tuberculosis.

Dr. R. M. Smith: (Answering Dr. Bowditch.) It is a question of general hygiene and supervision. Many children who present evidences of being below par and who are treated by coöperating with the school nurses and by frequent visits to see if the rules laid down are carefully followed, get back soon into a favorable condition. It is very much the same kind of treatment as for tuberculosis, but does not involve exclusion from school.

Dr. J. L. Morse: I came here tonight without the slightest idea of what this paper was to be about and without ever having exactly formulated my ideas on the subject. If I had written the paper myself I could not, however, have expressed them as well as Dr. Hawes has expressed them for me. My attitude in dealing with students has come to be much the same regarding tuberculosis as syphilis. Every time a student sees a baby with snuffles from a cold in its head, a pimple on its face, or an erythema from wet diapers, he says it has syphilis, and every time he sees a child with a cough or a temperature above normal he says it has tuberculosis. I find it necessary, therefore, to devote a great deal of time to prove to them that these symptoms do not necessarily mean that they have either one or the other. In my own experience, when a child sweats at night, instead of thinking of tuberculosis, I find out whether the windows are open or not, how many blankets it has over it, whether it has adenoids, and a few other things of that sort. Now as to fever, and whether a temperature of 99 or 99.4° F. is a fever. I am inclined to think that if we took a series of normal children and took their temperature right through the day we would find, especially if they had been playing hard or had been excited, that they had a temperature above 99° F. a good deal of the time. That is, a slight elevation of temperature is a very common thing from minor causes, and a little temperature does not necessarily mean tuberculosis. My point is that when a child has a slight temperature, the chances are that there is some other explanation for it than tuberculosis and that tuberculosis should be thought of only when every other cause has been excluded. The cause of the temperature is much more likely to be a little adenoid infection, some infection in a sinus, a mild pyelitis, trouble in the ears, or something of that sort, than tuberculosis. A word as to d'Espine's sign. This almost always means enlargement of the tracheobronchial lymph nodes. The fact that they are enlarged does not, however, necessarily mean that they are tubercular. X-ray pictures do not always prove positively that they are enlarged, for unless the observer understands how to interpret the findings correctly, much confusion is likely to result. Coming to the tuberculin test, I have always felt that a negative tuberculin test, carefully done, was pretty good proof that a child did not have tuberculosis, and I am still inclined to feel so. Another thing to be remembered in connection with the tuberculin test is that the combination of signs in the lungs and a positive tuberculin test does not prove that the process in the lungs is tuberculosis. I have seen a large number of children condemned to death by house officers on account of such a combination, and the children recover completely afterwards.

Dr. Marshal Fabyan: Apropos of what Dr. Talbot has said about infection from milk, perhaps it

would be of interest to the society to know that in the last few instances of the tuberculous material sent us, consisting of tonsils and cervical glands of young children, the bovine strain has been isolated.

In regard to what Dr. Morse has said concerning the tuberculin test, I would mention that we recently received a large tuberculous gland which had been removed from the neck of a cow. This cow was three years old and had received the tuberculin test twice yearly without ever giving a positive reaction.

DR. CLEAVELAND FLOYD: I think a recent article by Dr. Hess of New York is pertinent here. A series of babies in a ward, were tested on entrance with tuberculin and were found to be negative. They were under the care of a nurse, who was later found to have a well marked case of active tuberculosis. She was discharged. These children were again tested at the end of three months, and a large proportion of them, who had been under that nurse's care, gave a definite positive reaction, showing how soon, at least in this series of cases, these children were sensitized to tubercle bacillus.

I was much interested in Dr. Morse's remarks about temperature. I think it is quite an important sign where it occurs in the morning and afternoon, and especially if you can rule out infection of the urinary tract, ears, etc. Again, you see a large number of children who in spite of overexcitement do not have a temperature. We have felt that persistent temperature in the afternoon, and frequently mornings, was of considerable importance as pointing to an active process in the lungs.

In the work that I have been interested in, the x-ray man has not known what the clinical ideas were on the patient at all. The case has been brought to him to x-ray. We have gotten his opinion before he knows about the case. This is the only way to get a fair and impartial interpretation of the plates. In some cases the d'Espine sign may be due to enlarged thymus glands.

DR. J. B. HAWES, in closing: I have little further to add to the discussion, except that I feel justified in having presented this paper in that it has brought up such valuable discussion, which, after all, is the important part of any paper. Dr. Bailey has a very broad and idealistic point of view in this entire matter; he goes rather further than I can at the present time, at least. Dr. Richard Cabot has said that if you want to get attention drawn to any one subject, "you must raise the devil of a row" about it. I think, therefore, we owe a vote of thanks to the little patient who has been the innocent cause of bringing up this matter before us.

DR. W. B. SWIFT read a paper entitled,

A VOICE SIGN IN CHOREA.

ABSTRACT: A definite and final description in literature of the choreic voice found absent to date. Methods of approach unscientific. Review of literature from 1841. Brief presentation of what the vocal kymograph can register. Demonstration of voice curves. Deductions therefrom as evidence of a new sign in chorea elicited quickly with an easy technic. (For full report see *American Journal, Diseases of Children*, 1914.)

DR. W. B. SWIFT, in closing: I wish to add in closing that the length of the test is merely to bring out more noticeably the voice change. In the talking voice the same change is so short in duration as hardly to be observed without difficulty. This may account for the vagueness in description and the absence of its observation up to date in the literature, and the reason it was found more definitely here was on account of the new method which was used,—the prolongation of the sound and the vocal kymograph.

Book Reviews.

Orthopedics in General Practice. By PROF. ADOLF LORENZ, Regierungsrat, director of the Imperial University Ambulatorium for Orthopedic Surgery in Vienna, and DR. ALFRED SAXL assistant surgeon in the Imperial University Ambulatorium for Orthopedic Surgery in Vienna. Authorized translation from the German by L. C. PEEL RITCHIE, Ch.M., M.D., F.R.C.S., Edin.; late voluntar arzt in the Imperial University Ambulatorium for Orthopedic Surgery in Vienna; tutor in clinical surgery, University and Royal Infirmary, Edinburgh. New York: William Wood and Company. 1913.

The preface by Prof. Lorenz points out many of the conditions in which a knowledge of what may be called orthopedic pathology may be of great help to the internist. Lorenz says that his friend, Prof. Lothar von Frankl-Hocwart, has expressed a wish that some book be written on the subject of Orthopedics in Medical Practice, and that with the editorial collaboration of Prof. Lorenz, Dr. Alfred Saxl has undertaken the fulfillment of this wish.

There follows a discussion of the various orthopedic conditions which may accompany or predispose to diseases of the different systems of the body, namely, respiratory, circulatory, digestive, urinary, nervous, locomtor, etc.

The book serves to call attention to a wide range of diseases in which familiarity with the commoner orthopedic lesions may be of great value to the internist. One gains the impression that the authors believe that these static conditions and structural skeletal changes may actually be the remote cause for diseases heretofore supposed to be primary in the organs affected. There is a growing tendency of orthopedic surgeons to agree with this belief.

The book is intended chiefly for internists, and the orthopedic conditions concerning which there is a difference of opinion as to treatment, etc., are not dogmatically discussed. The wide familiarity with the literature, chiefly European, is shown. We commend the book to the internist

and general practitioner. We should be grateful to Dr. L. C. Peel Ritchie for his careful translation of the book into English.

A Clinical Manual of Mental Diseases. By Francis X. Dercum, M.D., Ph.D., professor of Nervous and Mental Diseases, Jefferson Medical College, Consulting Neurologist to the Philadelphia General Hospital, etc. Philadelphia and London: W. B. Saunders Company. 1913.

This work has been prepared from a purely practical point of view to enable the general practitioner, the family physician, to recognize mental diseases in their early stages, to know what to do under given conditions, when to commit and when not to commit the patient to a hospital and how to treat him at home or elsewhere outside of an institution, when this is practicable. In this the author has been unquestionably successful, giving excellent clinical pictures of the different forms of the disease and many details of treatment, all of which cannot fail to be of real help in diagnosis, prognosis and treatment, including a number of important points which have escaped other writers. His nosology, however, adds more new and unnecessary terms to confuse the learner, his diagnosis is not wholly complete, as in the matter of the differentiation between manic states and dementia precox, and in his attack upon the teachings of Freud he fails to credit psychoanalysis with many of its advantages in diagnosis and treatment. A chapter on methods of mental examination, also, would not have come amiss. But these are minor defects beside the real and practical merits of this useful manual of mental diseases.

Operative Surgery. For Students and Practitioners. By John J. McGrath, M.D., clinical professor of surgery, Fordham University; professor of operative surgery, New York Post-Graduate Medical School; consulting surgeon to the People's Hospital; visiting surgeon to the Harlem and New York Foundling Hospitals; Fellow of the New York Academy of Medicine; member of the American Medical Association. Fourth revised and enlarged edition, with 364 illustrations, including full-page color and half-tone. Philadelphia: F. A. Davis Company, Publishers. 1913.

Since the previous edition many new illustrations appear and much new matter has been added to the text. It is probably true that every teacher of medicine develops, in the course of time, certain individual methods in the presentation of his particular subject, which appeal to him more than the methods of other teachers. He, therefore, finds it desirable to assemble in a text-book the facts and theories in the manner in which he has been able to present them most convincingly to his students. This is the reason why many text-books on both medicine and surgery appear; not because they add anything definitely new nor that they contain essentially new procedures, nor even at times that they represent a ripe personal experience. Dr. McGrath has caused to be published a compact, well printed and well illustrated volume of eight hundred pages. It seems to contain all that is essential for the average student. Operations which come under the general class of emergencies are described with much detail. The book is divided into ten parts, based on an anatomical classification. On the whole, the volume does not present features which distinguish it particularly from a considerable number of well known text-books.

The Operating Room and the Patient. A Manual of Pre- and Post-Operative Treatment. By Russell S. Fowler, M.D., chief surgeon First Division German Hospital; surgeon, Methodist Episcopal Hospital; consulting surgeon, Hebrew Orphan Asylum, Brooklyn, N. Y. Third edition. Philadelphia and London: W. B. Saunders Company. 1913.

Dr. Fowler has in this edition written a volume of six hundred pages, profusely illustrated. It includes a list of instruments and dressings commonly employed in some eighty surgical procedures and completed by an extensive index. The numerous illustrations, most of them taken from the author's text-book on surgery, are in a very large measure half-tones, well chosen and satisfactory. The printing is clear and sharp and the book is of convenient size. The illustrations of bandaging are particularly to be commended. In his preface he says, "It has been my purpose to simplify the technic as much as is compatible with careful work and to present the subject in a terse, yet I hope, readable manner."

He summarizes the underlying principles of surgical treatment as follows: "Careful anesthesia, exact hemostasis, asepsis, rest of the injured part, use of the rest of the body, feeding advanced to normal as fast as the anesthetic weakened stomach can care for it, and the following of the general rules of hygiene."

These underlying principles are unquestionably correct. The author has been unusually successful in his effort to make the book terse, and it may be unhesitatingly recommended to students and to young surgeons.

THE BOSTON

Medical and Surgical Journal

THURSDAY, MAY 21, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

MEDICAL LEGISLATION. ANTI-VACCINATION AND THE BAGSHAW BILL.

IN the issue of the JOURNAL for April 2 (p. 559) we published a communication from Dr. George W. Gay, in behalf of The Massachusetts Medical Society, on "Anti-Vaccination and the Legislature"; and in the issues for April 23 (p. 664) and April 30 (p. 697) we commented editorially on the Bagshaw vaccination bill (House No. 1018), which has been passed by the Senate of the General Court. In another column of this week's JOURNAL we publish a second letter from Dr. Gay, describing in the recent experience of Niagara Falls the inevitable result of anti-vaccination legislation of the type of which the Bagshaw bill is an example. Another instance of such experience may be cited in the case of the state of Minnesota, which, with voluntary vaccination and a population of 2,000,000, had in 1912 2320 cases of smallpox, while Massachusetts, with compulsory vaccination and a population of 3,400,000, had in the same year only 218 cases.

Meantime the passage of the Bagshaw bill by the House has fortunately been delayed. At its session on May 7 the House voted to postpone action for one week in order that the replies made by the State Board of Health to a series of questions on vaccination, addressed to it by the legislature, might be printed and examined by the members. In these replies the board states that if any legislation affecting vaccination be needed, it should be more, not less, stringent than at present. The board also says that it is emphatically not desirable to enact a law requiring any particular method of vaccination to the exclusion of other methods. To the question whether vaccination is a harmful procedure, and if not, what is its chief danger and how may it be obviated, the board replies:—

"Vaccination is not in itself a harmful procedure, but the wound may be susceptible to infection from without if it is not properly cared for and protected. Vaccination is always to be considered as a minor surgical operation to be carried out under conditions of strict asepsis."

At a recent meeting of the Boston district of the Massachusetts Homeopathic Medical Society the following resolution relative to the anti-vaccination bill was unanimously adopted:—

"Resolved, That this society is strongly opposed to the bill now before the legislature allowing unvaccinated children to attend the public schools, knowing that such a law would be a serious menace not only to such pupils, but to the public at large."

The attitude of the regular profession on the subject is of course unquestioned. It is earnestly to be hoped that the House will not enact into law the pernicious provisions of the Bagshaw bill.

Since the above was in press, the House has defeated the Bagshaw bill by a vote of 132 to 53.

FOUR NATIONAL MEDICAL MEETINGS.

THE tenth annual meeting of the National Association for the Study and Prevention of Tuberculosis was held on May 7 and 8 at Washington, D. C. At the opening session, Dr. Charles J. Hatfield, of Philadelphia, reviewed the progress of the past decade, since the organization of the society. During this time there have been established throughout the country over 2000 anti-tuberculosis agencies, including 1200 anti-tuberculosis associations, 550 sanatoria and hospitals, 410 dispensaries, and 250 open air schools and classes. At the session on May 8, Dr. Edward Archibald, of Montreal, read a paper on the application of pulmonary surgery to the treatment of tuberculosis; and the Massachusetts method of caring for consumptives was described in papers by Dr. Walter C. Bailey and Dr. John B. Hawes, 2nd, of the

board of trustees of the state hospitals. Dr. W. L. Moss, of Baltimore, and Dr. S. H. Gilliland, of Marietta, Pa., described their experimental investigations on the possible immunization of cattle and children against tuberculosis. At the closing session the following officers were elected for the ensuing year.

"Dr. George M. Kober, Washington, D. C., was elected president and Surgeon-General Rupert Blue of the public health service was made a member of the board of directors. Other officers elected were: Dr. Lee K. Frankel of New York and Dr. Jarvis Barlow of Los Angeles, vice-presidents; Dr. Henry Barton Jacobs of Baltimore, secretary; and William H. Baldwin of Washington, D. C., treasurer. Seattle, Wash., and Chicago were urged for the meeting place next year, but no decision was reached."

The American Neurological Association held its yearly meeting from May 7th to 9th, inclusive, in Albany under the presidency of Dr. Henry Hun. Papers of importance were read on surgery of the central nervous system and on more recent methods of treatment of late nerve syphilis.

The annual meeting of the American Society for the Advancement of Clinical Investigation was held in Atlantic City, N. J., on May 11 and 12. Papers were presented by Dr. George Draper, of New York, on the treatment of tabes by intravenous and intraspinous injection of salvarsan; by Dr. O. M. Schloss, of New York, on blood changes produced by feeding foreign protein; and by Dr. E. W. Bridgman, of Baltimore, on the third heart sound.

The annual meeting of the American Association of Physicians was held in Atlantic City on May 12 and 13. Papers were presented by Dr. Simon Flexner, of New York, on the isolation of the organism of poliomyelitis; by Dr. Franklin W. White and Dr. Ralph D. Leonard, of Boston, on the use of the x-ray in the diagnosis of cancer; by Dr. Julius Fridenwald, of Baltimore, on the results of a series of one thousand cases of cancer of the stomach; and by Dr. Richard P. Strong, of Boston, on the transmission of the virus of verruga to the lower animals. At the closing session, Dr. S. J. Meltzer, of New York, was elected president of the Association for the ensuing year, and Dr. Henry Sewell of Denver, Colo., vice-president. The remaining present officers were reëlected. A full report of the proceedings of this Association will appear in a later issue of the JOURNAL.

THE MEDICAL SITUATION IN MEXICO.

DURING the uncertainty pending mediation in Mexico active hostilities continue between the federal and constitutional forces about Tampico, with considerable casualty on both sides. The United States occupation of Vera Cruz is complete, and comprehensive plans for the sanitation of the city are already being carried out. Surgeon-General Gorgas has detailed Major T. C. Lyster and Major Robert A. Noble to undertake this work, both of whom have had experience in the Panama Canal Zone. The Public Health Service has detailed Dr. Gregorio Guiteras to Tampico and Dr. R. H. von Ezdorf to Vera Cruz. Twenty American Red Cross nurses have also been ordered from Washington to take charge of the nursing in the military hospital at Vera Cruz. At Mexico City the American civil hospital is still open, and the American physicians and nurses remain in charge of the patients. At Galveston, Texas, the United States government has conditionally leased a large bathing pavilion to be remodeled into a hospital.

"The house is three stories high, 100 by 150 feet, and has room for 1400 persons now. The government option provides for another story, if that is needed, so the remodeled structure could accommodate 2000 wounded. In case more troops are moved to Mexico and there is hard fighting, all the wounded would be brought to this hospital for treatment."

Meantime, the United States naval hospital ship *Solace* was lying off Vera Cruz, under command of Dr. L. W. Spratling of the navy medical corps, ready to receive immediately any wounded sailors or marines for care or transport.

"The *Solace* has three isolation wards for contagious diseases with a capacity of 30 patients, rooms for nine officer patients, and wards accommodating 68 medical patients and 76 surgical patients. It has an operating room with two operating tables, an eye, ear, nose and throat examining room, a bacteriological and chemical laboratory, a dental laboratory, a cooled morgue in the after end of the ship, and quarters for the medical staff and crew."

On May 14 the *Solace* brought to New York 101 sick and wounded sailors and marines, 68 of whom were landed and sent to the Naval Hospital. After refitting, the *Solace* will sail again on June 9 to return to Vera Cruz.

MEDICAL LEGISLATION. REORGANIZATION OF THE MASSACHUSETTS STATE BOARD OF HEALTH.

IN another column of this issue of the JOURNAL we print in full the text of the proposed bill for the reorganization of the Massachusetts State Board of Health, as drafted by Dr. Rosenau, and submitted by the Governor with a special message to the General Court. This bill has already been reported favorably by the legislative committee on public health, five of the eleven members, however, reserving their right to dissent. On Friday of last week, May 15, the councillors of the Massachusetts Medical Society, and other physicians interested in public health matters met Governor Walsh at the Boston Medical Library to discuss the bill. In connection with this discussion the name of Dr. Victor G. Heiser, of the United States Public Health Service, was mentioned as a probable candidate for the position of Health Commissioner.

DR. WALCOTT'S RETIREMENT FROM THE BOARD OF HEALTH.

ON May 19 Dr. Henry P. Walcott's term of office as a member of the Massachusetts State Board of Health expired. After thirty-three years of faithful and distinguished service on this important board, much of the time as its chairman, Dr. Walcott is unfortunately not a candidate for reappointment. Indeed the personal sacrifice he has already made for the welfare of the community is greater than might be asked of any man, and merits the appreciative and lasting gratitude of the public and of the profession.

Upon this occasion of Dr. Walcott's retirement, an address, signed by about twenty-two hundred Massachusetts physicians, was presented to him expressing their grateful sentiments and regard. This address, which is published in full in another column of this issue of the JOURNAL, so adequately states the feelings of the profession and the merit of his service that nothing can here be added to its deserved tribute. The standard set by Dr. Walcott's predecessors in affairs relating to public health was greatly creditable to this Commonwealth, and was everywhere recognized by sanitarians; his own discharge of the duties of the office not only has been worthy of them, but makes increasingly difficult the responsibilities of his successors. His was a type of fidelity and devotion not always manifested in unpaid public office, the type

> "in which appears
> The constant service of the antique world,
> When service toiled for duty, not for meed."

MEDICAL NOTES.

HONOR FOR DR. FLEXNER.—It is announced that the President of the French Republic has recently conferred the cross of chevalier of the legion of honor on Dr. Simon Flexner, director of the Rockefeller Institute for Medical Research, for his services to science in the treatment of epidemic cerebrospinal meningitis.

AWARD TO DR. GORGAS.—It is announced that the American Museum of Safety has recently awarded the Dr. Louis Livingston Seaman medal to Dr. William C. Gorgas, surgeon-general of the United States Army, for his work in making the Panama Canal Zone sanitary and habitable.

A WELSH CENTENARIAN.—Thomas Morris, of Westernville, Neb., is locally reputed to have been born on Jan. 15, 1794, at Berriew, Montgomeryshire, Wales. He followed the cobbler's trade in his native village until 1871, when he migrated to the United States and became a farmer. He drinks tea and coffee, is still able to walk, and reads with the aid of glasses.

LONDON DEATH-RATES IN MARCH.—Statistics recently published show that the total death-rate of London in March was 152 per 1000 inhabitants living. Among the several districts and boroughs the highest rate was 20.3 in the old city, and the lowest was 10.1 in Lewisham, a populous southern residential region.

BOSTON AND NEW ENGLAND.

TWO LIVING CENTENARIANS.—Mrs. M. J. Lavin of Melrose, Mass., is said to have been born on May 9, 1814, in Prince Edward Island. She was married in 1837 and has had six children, of whom three are living, with 15 grandchildren and 6 great-grandchildren.

Benjamin Priest, of Canaan, Somerset County, Maine, is said to have been born on May 12, 1811. He is the oldest living veteran of the Civil War.

Long Island Hospital.—The Long Island Hospital, Boston, is in need of new buildings.

"Two years ago the city council appropriated $77,000 for new buildings, and last year $210,000. The construction of a new central kitchen with connecting subways to the different buildings, an addition to the men's dormitory and alteration of the women's dormitory have been undertaken. These building operations will give much relief to the crowded conditions, but further construction, in the opinion of the trustees, should be undertaken at once.

"The institution suffers from lack of sufficient nurses. The present nurses' home will not permit an increase in the number of tenants and, until a new building is constructed, the trustees will be obliged to get along with the present number. Another need is a maternity hospital and nursery separate from the main hospital, and to this use it is planned to put the present nurses' home. The plans already adopted call for a nurses' home and for hospital and dormitory pavilions. The architects estimated that these buildings could be erected within the appropriation of $287,000, but this was found impossible. The amount of money now demanded for the new buildings is $111,951."

Scarlet Fever in Bedford.—Report from Bedford, Mass., on May 10, states that the epidemic of scarlet fever in that town is ended and the quarantine raised.

Jubilee of Massachusetts Dental Society.—The fiftieth anniversary and annual meeting of the Massachusetts Dental Society in Boston on May 7 were attended by about sixty members. The history of the society was reviewed in a paper by Dr. Waldo E. Boardman, of Boston; an address was delivered by the outgoing president, Dr. Aurelius F. Wheeler, of Worcester; and one on "The Relation of the State and District Societies," by Dr. Thaddeus P. Hyatt, of New York City. The following officers were elected for the ensuing year: president, Dr. Henry H. Piper, of Somerville; secretary, Dr. A. H. St.C. Chase, of Everett, and treasurer, Dr. Joseph T. Paul, of Boston. The society voted to raise the sum of $10,000 towards the national fund for establishing and directing oral and dental research.

Recent Mortality Rates in Boston.—The Boston health department's mortality report for the first four months of this year shows an increase of 69 deaths over the corresponding months of last year, but the death-rate shows a drop from 17.90 to 17.81 of 1000 population. The infant mortality for the same period this year shows a decrease of 77.

Deaths thus far this year number 4396 against 4327 last year. Of that number 439 were victims of tuberculosis in all forms, a decrease of 16 compared with the figures of the first four months of 1913; typhoid 30, a gain of 14.

Of 58 diphtheria victims, six were non-residents, while the same number of scarlet fever victims were residents of other municipalities.

The number of children under one year who died during the first four months of this year was 651, against 728 for the corresponding period of last year.

From broncho-pneumonia there were 85 deaths, a decrease of 22; pneumonia, 60.

Hospital Bequests.—The will of the late Mrs. John M. Harlow, of Woburn, Mass., which was filed on May 7 for probate at Cambridge, Mass., contains considerable bequests to the Massachusetts General Hospital and the Boston Medical Library. To the Woburn Charitable Association is left a fund of $20,000 for erecting a surgical building to be known as the Dr. John M. Harlow Surgery, and to be used in conjunction with the Charles Coate Memorial Hospital of Woburn.

The wills of the late Emily and Eliza A. Conant, of Concord, Mass., who died on April 28 and May 2, respectively, were filed simultaneously last week for probate. They contain a bequest of $5000 to the Deaconess Hospital, of Concord, for a free bed, to bear the names of both testatrices.

The will of the late Esther F. Hannum, of Cambridge, Mass., who died on May 5, was filed on May 13, in the Middlesex probate court. It contains bequests of $2000 each to the Cambridge Hospital and the Cambridge Visiting Nurses Association, and $1,000 to the Holy Ghost Hospital, Cambridge.

Roentgen Society of New England.—The Roentgen Society of New England was formed at a meeting of about twenty roentgenologists, held at the office of Dr. A. W. George of Boston, May 6, 1914. An organization was effected and the regular program will begin in the fall. The officers elected were, the executive committee: chairman, Dr. A. W. George; Dr. Walter J. Dodd, Dr. Samuel W. Ellsworth; secretary, Dr. Ralph B. Leonard, all of Boston.

MASSACHUSETTS COLLEGE OF PHARMACY.—The annual graduating exercises of the Massachusetts College of Pharmacy were held in Boston on Thursday of last week, May 14. The principal address was made by Mr. Samuel W. McCall. Diplomas were awarded to 39 students, 4 of whom are women.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending May 12, 1914: (Diphtheria, 45, of which 2 were non-residents; scarlatina, 107, of which 18 were non-residents; typhoid fever 6; measles, 114, of which 2 were non-residents; tuberculosis, 59, of which 5 were non-residents.

The death-rate of the reported deaths for the week was 15.49.

NEW YORK.

NEW YORK BOTANICAL GARDEN.—May 7 was a field day at the New York Botanical Garden, Bronx Park, in honor of the Woman's Auxiliary of the Botanical Society. On the reception committee of the board of managers were Drs. W. Gilman Thompson, Frederic S. Lee, and Lewis Rutherford Morris, and after the members and guests had visited all parts of the extensive grounds, riding and walking alternately, tea was served and an address of welcome given by Dr. Thompson in the museum building. The tea was made from the leaves of plants actually grown in the garden, and an interesting feature of the occasion was the presentation by Dr. Reginald H. Sayre of a series of old Chinese paintings showing the process of preparing tea. In addition, Dr. N. L. Britton, director-in-chief of the garden, gave, in concise form, some idea of what the New York Botanical Garden is, with its 250 acres of land, 4 miles of driveways, 8 miles of footpaths, 75 acres of natural forest (including the wonderful hemlock forest), 100 acres of shrubs, 20 acres of lawns and meadows, over a mile of herbaceous beds, 6 to 10 feet wide, with 3,000 varieties of plants; in addition to the immense greenhouses containing more than 8,000 kinds of plants, and the palm house, with 130 varieties of palm.

BETH ISRAEL HOSPITAL.—The Beth Israel Hospital, now located at Cherry and Jefferson Streets, far down on the east side, has purchased for the erection of a new hospital building a site on Livingston Place, fronting on Stuyvesant Square. The plot has an area of some 14,000 square feet, and, in addition to the price of the land, the cost of the new structure will be about $1,000,000. The institution, which was founded in 1890, has outgrown its present quarters, and in the building on Stuyvesant Square there will be 500 beds, besides ample provision for dispensary service.

BRONX CONTAGIOUS HOSPITAL.—A hospital for contagious diseases in the borough of the Bronx, the population of which is approximately 600,000, is now assured, the board of aldermen having authorized the purchase, as a site for the purpose, a tract of thirty-three acres in the upper part of the borough, known as "Seton Falls Park." In July, 1911, the Board of Estimate and Apportionment voted an appropriation of $125,000 corporate stock for such a hospital, but in consequence of vigorous protests made by local taxpayers, action was deferred. This appropriation is now available for the construction of the first hospital building. The Health Department has arranged to have smallpox vaccination performed daily at all its children's clinics, and also, on two days of the week, at each infants' milk station. This action will create 62 offices of the department where vaccination may be obtained free of charge. In view of the mutual interests existing between the health authorities and life insurance companies in the promotion of public health, these companies have been found willing to coöperate cordially with the Health Department in carrying on an extensive educational campaign among the people of the city. Already, the Metropolitan and Prudential companies have placed the services of their agents at the disposal of the department for the distribution of public health literature. The department has often found it difficult to quickly reach large numbers of persons, but the action of these two companies alone means approximately 3,000 agents visiting 750,000 families weekly.

FUND FOR NEW YORK UNIVERSITY.—It is announced that a donation of a trust fund of $10,000 has been made to New York University by Mrs. Helen H. Le Fevre, widow of Dr. Le Fevre, the late dean of University and Bellevue Hospital Medical College. The trust is to be known as the Egbert Le Fevre Deanship Fund, and the terms provide that the income is to be applied toward the salary of the incumbent of the deanship of the school. Although it is definitely so stated, the income of the fund may be added to the salary at present received by the dean. In

making the gift, Mrs. Le Fevre stated that she wished in some way to assist in perpetuating the memory of her husband, and expressed the hope that the fund would prove of material benefit to the institution in which Dr. Le Fevre was so deeply interested, and to which he devoted so much work and time during the best years of his life.

7. Rongy and Arluck discuss the clinical use of pituitrin, its abuse and its dangers, as they view them in the light of their experience with some three hundred cases. They advise conservatism in using the drug. It does not induce labor pains, but does increase their intensity and frequency after labor has started. A single dose may be used as an adjuvant in cases where pregnancy is interrupted by catheter or bag. Pituitrin should not be used early in the first stage, as its action is too transient. It is contra-indicated when inertia is complete, on account of the danger of uterine rupture, also in cases of dystocia due to malposition or obstruction. The cervix must be dilatable, the presenting part engaged, and a general anesthetic at hand. The drug should not be used in cases where a sudden rise in blood-pressure may prove dangerous, and should be used with caution when the fetal heart sounds are feeble or irregular.

1. Russell states that the prophylactic antityphoid vaccination as used in the army has given almost absolute protection against typhoid without producing untoward effects of any character.

2. Crile advocates immediate closure of the common bile duct after removal of stone, instead of drainage, and believes if this is carefully done both morbidity and mortality will be lessened.

4. Smyth's article is a detailed and interesting review of the very important subject of the cultivation in vitro of tissue cells. It is an interesting article.

7. Cadwalader finds the following in regard to cerebral hemorrhages: Spontaneous intracerebral hemorrhages are apt to be large; very small hemorrhages are rare. Large hemorrhages are always fatal; small ones may be, and it seems probable that hemorrhages are always fatal whether large or small. When repeated attacks of apoplexy with hemiplegia occur in the same patient at different times, the final or fatal attack may be due either to softening or to hemorrhage, but the former non-fatal attack is invariably caused by vascular occlusion and softening, not by hemorrhage. 9. Contraluesin is a proprietary combination prepared by Richter, of salicylic acid, sozojodol, quinine, corrosive sublimate, arsenic, phosphorus, and colloidal mercury. It is administered by intramuscular injection. Klausner has used this drug on 300 patients, making about 2000 injections. From this series he concludes that contraluesin reacts favorably on syphilis in all its stages and is of especial benefit in abortive treatment if combined with salvarsan. The preparation has no bad effects on the kidney, is nonirritating locally and has only trivial accessory effects.

10 and 11. V. Schubert and Gennerich describe a technic, which is essentially the same, for injecting salvarsan or neo-salvarsan into the spinal cord in a dilute solution of cerebro-spinal fluid or saline. Both authors believe that if this form of treatment is given properly as good results are obtained as with the Swift-Ellis method, without ill consequences, and with the advantage of greater simplicity. [R. F.]

9. ZÄNKER, W., AND SCHNABEL, K. *Modern Surgical Dressings.*

3. Stern describes, as a not uncommon finding in hypothyroidism, an edematous infiltration of the mucous membrane of the lower urinary tract, this condition giving rise to polyuria, tenesmus and strangury. Frequent and painful micturition may be the only subjective symptom of the condition in its early stages, and this, together with intractable enuresis, either in children or adults, should indicate cystoscopy and investigation of the functioning of the thyroid. These symptoms are relieved by the administration of thyroid extract.

6. Grotan is a complicated synthetic compound of cresol, chlorine and sodium. It is easily soluble in water, of an alkaline reaction, has no injurious action on skin, does not corrode instruments or destroy cloth, and experiments with guinea-pigs have shown that it has practically no poisonous action. The authors claim that in a 0.33% solution it rapidly kills the ordinary pyogenic organisms,—in a series of ten experiments with a solution of this strength the staphylococcus aureus was in each instance killed at the end of two minutes. It is put up in tablets, and for ordinary purposes four are used to a liter of water. If the authors' claims are true this should prove a useful and valuable disinfectant. [R. H. M.]

2. The author has examined with great care the blood in a series of cases; in 24 with pulmonary tuberculosis he has in 21 isolated an acid-fast bacillus which he feels confident is the tubercle bacillus. He rules out carefully the possibility of contamination or artefacts. In 26 non-tuberculous patients he was unable to isolate any acid-fast bacilli whatever. As a result of his own work, and a careful review of the literature, he concludes that clinical, anatomical and experimental findings all make it in the highest degree probable that tubercle bacilli can at one time or another be found in the blood in all sorts of tuberculous cases.

3. The author reports two cases of alcoholics,—one a chair-maker and one a painter—both of whom died with gastric symptoms, and in each there was a huge shellac cast of the stomach, resulting from drinking polish or other articles of their trade. [R. H. M.]

7. Lesser believes in early and energetic treatment of syphilis by the combination of mercury and salvarsan in all forms of the disease, including tabes, though he says that good results have not as yet been attained in general paralysis. He gives 3 or 4 injections of salvarsan at intervals of 10 to 14 days. He thinks that in the acute secondary stage with general symptoms salvarsan may cause severe toxic symptoms, and should be preceded by several days of mercury alone. Intermittent treatment is advisable. He states that severe toxic symptoms from salvarsan undoubtedly arise in some cases,—Mentberger collected 87 cases, up to August, 1913, which had either very severe after-effects or else died.

18. Laache reports three interesting cases as follows: One, parotitis (right) in the course of an acute bleeding gastric ulcer; two, double parotitis associated with an acute appendix; and three, suppurative parotitis (left) with paralysis of the facial nerve, in a case of salpingitis. He mentions several theories, but can advance no good explanation of these associated conditions.

19. The author presents five cases of a large series of breasts, which were removed for constant and intractable pain, and which on pathological examination showed more or less complete senile atrophy of all the glandular elements, though none of the patients were over 44, and two were under 40. Histological examination revealed no definite cause for the pain. In conclusion he suggests that pre-senile involution must be considered a definite clinical and pathological condition, associated with severe pain, and hopes for a more extensive and detailed knowledge of the condition as soon as more cases are collected. 5. Kahn has worked with the method for testing heart function that was instituted by Waldvogel. The method consists in noting the difference in systolic blood-pressure in the same patient between lying and standing. He has tried the test out on a good many normal and pathological conditions and has charted the cases to show the difference in pressure dependent upon the initial height of the pressure. He feels that this method is practical and of a good enough accuracy for clinical purposes. The chief feature is that it can be used in the office as well as in hospitals. The normal limits are a rise of from 5-15 mm. in pressures that are from 60-100 mm. In pressures from 100-130 mm. the normal variation is from an increase of 15 to a drop of 5 mm.

7. Dorner has studied the importance of indican in the blood and body fluids as a diagnostic aid in diseases of the kidney. The test is a simple one and only requires from 10-20 c.c. of blood. Considerable amount of indican in blood serum means marked uremia. If present in the blood it is also present in the fluids from the pleural cavity and other edematous fluids, but not in the cerebro-spinal fluid. The indican apparently does not play a factor in the toxicity of the blood serum in uremia. With large amounts of indican in the urine none will appear in the blood when no nephritis exists. The liver is not the only place in which urinary indican is formed. Apparently the kidneys take part in its formation. Usually the detection of this substance in the blood means that death is near, but some cases improve after the demonstration of it. [C. F., JR.]

5. VENTRE, J. *Influence of Artificial and Natural Media on Different Species of Saccharomyces.*
6. D'HERELLE, I. *The Cocco Bacillus of the Grass-Hopper.*

3. Manonélian has been working at the Pasteur Institute on the presence of the typical negri bodies of rabies in the nerve ganglions of the salivary glands. As a result of his studies he concludes that these bodies exist in the cytoplasm of the nerve cells in these intraglandular ganglions, but that they never appear in the parenchymatous cells of the acini or of the excretory ducts. The acini undergo, however, profound changes with necrosis and absorption of the necrotic material by endothelial phagocytes so that the glands may be replaced by the phagocytic cells. The phagocytic cells are seen in the saliva.

4. Danyse has been endeavoring to improve the toxicity of chemical bodies for certain human parasites without increasing the toxicity for the human host. For this purpose he has been adding salts of silver to different arsenic compounds and studying the effect experimentally and in certain human cases, especially general paresis. He gives a list of the results of these different compounds upon several types of spirilla and trypanosomes, and also upon lesions from the treponema pallidum in men and in rabbits. He concludes that the addition of bromide and iodide of silver to dioxydiaminoarsenobenzol increases the antiseptic and curative properties of all three without augmenting their toxic properties. He feels that these chemical compounds are not the only antiseptic power at work, but that the phagocytic power of the host is most important in destroying the microbes. [C. F., JR.]

Miscellany.

AN ACT TO CREATE A STATE DEPARTMENT OF HEALTH AND TO AMEND THE PUBLIC HEALTH LAWS.

The following is Governor Walsh's message transmitting to the legislature his bill for the reorganization of the State Board of Health.

To the Honorable Senate and House of Representatives.

In my inaugural address I emphasized the fact that in the multitude of legislative matters which come before the State Legislature, there are none of greater significance or importance than those which are planned with the purpose of protecting the public health, for upon a sound, healthful and vigorous population depend in the greatest measure the prosperity, safety and welfare of the Commonwealth.

There is no greater service than the prevention of sickness and premature death, with all its concomitant sorrows and miseries. The human body is the most wonderful machine that is known and the maintenance of this delicate mechanism in full vigor, for its allotted time, is the end for which health officers, physicians, social workers and others are striving. The government should lead in this great work.

Most legislation is directed towards objects which interest only a certain percentage of the population of the State. Public health legislation is necessarily of interest to every man, woman and child in the Commonwealth. Even recognizing the wonderful advance in health conservation which has taken place in the past few decades, it is still obvious that preventable disease is the main cause of death. Massachusetts may well point with pride to its early recognition of the public health problems and the creation, in consequence, of a State Board of Health.

Without detracting from the past accomplishments of the State Board of Health, it has become obvious to many, including those who are in a position to recognize the State Board of Health's service, that the Board does not possess the necessary organization to cope with the present health problems of the Commonwealth. In a word it is in some ways seriously handicapped in being able to reach the highest efficiency that the people have reason to expect of a department of health.

In recent years tremendous strides have been made in public health work, yet Massachusetts is conducting this work under administrative machinery provided many years ago.

Other States have recognized defects similar to our own, and as a result we note the passage of acts in various States reorganizing the State health service along the most modern and effective lines.

Massachusetts must not lag in the forward march and in order that the citizens of the Commonwealth might have the greatest possible protection I have deemed it my highest duty to suggest a reorganization of the public health activities of the State.

The time has come in Massachusetts for a salaried Health Commissioner to superintend that work of the government which deals with public health administration. He should be a man who will devote his whole time, strength and energy to this problem, and should be a man "skilled in science and experienced in public health administration."

The accompanying bill is designed to give Massachusetts a most effective type of public health organization. It has been drawn up after consultation with experts from the United States Public Health Service, the Commissioner of Health of New York State, and many others, qualified by experience and training, who have given freely of their advice, in order that the proposed legislation might represent the very best thought in this vital matter. This proposed legislation calls for the abolition of the State Board of Health and requires the appointment of a State Health Commissioner who shall be directly responsible to the Governor. A Public Health Council is created, but following out modern beliefs in effective administrative work, this council has no administrative or executive powers.

Provision is also made in this bill that the district health officers be required to give their entire services to the Commonwealth and that the present unsatisfactory arrangement be discontinued, —namely, health officers half-paid and expected merely to give such time as they choose in their respective districts to this work.

Your especial attention is invited to the creation of three new divisions, one dealing with infant and child hygiene, the second with communicable diseases, and the third an administrative department for educational and publicity work. The need of special activities in the prevention of infant mortality is evidenced by the fact that in Massachusetts in 1912, out of a total of 52,250 deaths, 12,273 were under two years of age. It is well recognized that many of these infant deaths are preventable, and an active division of the State Department of Health should do much to cut down this enormous wastage of life.

Similarly the tuberculosis problem is of great magnitude, even though noteworthy decreases in its mortality rate have been apparent in the past; 5,151 citizens of of Massachusetts succumbed to this disease alone in 1912, or almost 10 per cent. of the total mortality.

Modern sanitary science recognizes that a great deal of preventable disease cannot be wiped out by the introduction of water purification plants or the enforcement of milk pasteurization, or similar public acts, but requires the *individual* cooperation of all persons. This makes it necessary that proper publicity work, especially by the State cooperating with local health authorities, be undertaken to bring before the people the simple facts, which they must know if they are to avoid contracting an unnecessary sickness. This important function is required in the proposed reorganization.

There should be no half measures in the fight for better public health conditions. This is a clear case where the best is none too good and it is believed that the passage of this bill will make it possible for Massachusetts to adopt all the latest modern methods of health conservation and possess the strongest and best Health Department in the country. I know of no greater service that this Legislature can render to those who have delegated to it the power to contribute to their happiness and welfare through the agencies and activities of government, than by adopting the proposed legislation.

Neither partisanship nor personal considerations can be permitted to move our minds when the well-being, the health, the very life of our people are at stake. DAVID I. WALSH.

Be it enacted by the Senate and House of Representatives, etc., as follows:

Section 1. There is hereby created a State Department of Health which shall exercise the powers and perform the duties now conferred and imposed by law upon the State Board of Health and Section 1 of Chapter 75 of the Revised Laws is hereby repealed. The State Department of Health shall consist of a Commissioner of Health and a Public Health Council. There shall also be directors of divisions district health officers, and other employees as hereinafter provided.

Section 2. The Commissioner of Health shall be appointed by the governor, by and with the consent of the executive council, and shall be skilled in sanitary science and experienced in public health administration. The term of office of the Commissioner of Health shall be five years; he shall receive an annual salary of seventy-five hundred dollars and his necessary traveling expenses, and shall devote his whole time to his official duties. The Commissioner of Health shall be the administrative head of the State Department of Health. His duties shall be to administer the laws relative to health and sanitation and the regulations of the Department; to prepare rules and regulations for the consideration of the Public Health Council; to appoint and remove directors of divisions, district health officers, inspectors, and other necessary employees, and fix their compensation within the limitations of appropriations therefor. Directors of divisions and district health officers shall be exempt from civil service regulations. The Commissioner of Health shall further submit annually to the Public Health Council a report with recommendations as to needed health laws, shall perform all executive duties now required by law of the State Board of Health, and other duties incident to his position as chief executive officer. He may direct any executive officer or employee of the State Department of Health to assist in the study, suppression or prevention of disease in any part of the Commonwealth.

Section 3. The Public Health Council shall consist of the Commissioner of Health and six members, hereimafter called the appointive members, at least three of whom shall be physicians to be appointed by the Governor, by and with the advice and consent of the Council. Of the appointive members first appointed, two shall hold office until May 1, 1915, two until May 1, 1916, and two until May 1, 1917, and the terms of office of the appointive members thereafter appointed, except to fill vacancies, shall be three years. Vacancies shall be filled by appointment of the Governor and Council for the unexpired term. The Public Health Council shall meet at least once in each month, and at such other times as they shall determine by their rules or upon the request of any two members. The appointive members shall receive $10. per diem while in conference and their necessary traveling expenses while in the performance of official duties. It shall be the duty of the Public Health Council to make and promulgate rules and regulations; take evidence in appeals; consider plans and appointments required by law; hold hearings; define the qualifications of local health authorities; submit annually to the Legislature through the Governor a report, including recommendations as to needed health laws; and to discharge other duties required by law; but it shall have no administrative or executive functions. The Public Health Council shall have power, by the affirmative vote of a majority of its members, to establish, and from time to time amend rules and regulations under the public health laws, the enforcement of which devolve on the State Department of Health. Every regulation adopted by the Public Health Council shall state the date on which it takes effect, and a copy thereof duly signed by the Commissioner of Health shall be filed in the office of the Secretary of the Commonwealth, and furthermore shall be published in such manner as the Public Health Council may determine. Rules and regulations so promulgated shall have the force and effect of law, and any violation thereof may be declared to be a misdemeanor, and punished by a fine of not less than one dollar nor more than one hundred dollars, or by imprisonment in the house of correction for a term not exceeding thirty days, or both. Upon request of the Public Health Council, the Governor is authorized to require the District Police to assist the State Department of Health in enforcing its rules and regulations.

Section 4. There shall be in the State Department of Health the following divisions, together with such other divisions as the Commissioner of Health may from time to time determine:—

1. Division of Administration.
2. Division of Communicable Diseases.
3. Division of Sanitary Engineering.
4. Division of Food and Drugs.
5. Division of Laboratories.
6. Division of Child Welfare.

The Commissioner of Health shall appoint and may remove, with the approval of the Public Health Council, a director to take charge of each division, and shall prescribe the duties of each division. The compensation of directors of divisions shall be fixed by the Commissioner of Health, within the limits of appropriations therefor, and subject to the approval of the Governor and Council.

Section 5. The Commissioner of Health shall, from time to time, divide the state into eight sanitary districts, and shall appoint a district health officer for each district, with the approval of the Public Health Council, at a compensation not exceeding $3500 per annum and necessary traveling expenses, and may remove the said officer. Said district health officers shall not engage in any other occupation and shall give their entire time to the performance of their duties. The Commissioner of Health may from time to time order two or more of said district health officers to work in one sanitary district in order to study, suppress or prevent disease. Each district health officer shall, under the direction of the Commissioner of Health, perform the following duties:—

1. Keep himself informed as to the work of each local health authority within his sanitary district;

2. Aid each local health authority within his sanitary district in the performance of his duties, and particularly upon the appearance of any contagious or infectious disease;

3. Assist each local health authority within his sanitary district in making an annual sanitary survey of the territory within his jurisdiction, and in maintaining therein a continuous sanitary supervision;

4. Call together the local health officers within his district or any portion of it from time to time for conference;

5. Adjust questions of jurisdiction arising between local health officers within his district;

6. Study the causes of excessive mortality or morbidity from any disease in any portion of his district;

7. Promote efficient registration of births, deaths and notifiable diseases;

8. Inspect, from time to time, institutions, schools, public conveyances, and labor camps within his district, and enforce public health laws and regulations in relation thereto;

9. Endeavor to enlist the cooperation of all physicians and welfare organizations within his district in the improvement of the public health therein;

10. Promote the information of the general public in all matters pertaining to the public health;

11. Act as the representative of the Commissioner of Health, and under his direction, secure the enforcement within his district of the public health laws and regulations.

Section 6. When in the opinion of the Public Health Council any local health authority shall fail or refuse to enforce the laws and regulations to prevent the spread of contagious or infectious disease declared by the Public Health Council to be dangerous to the public health, or when, in the opinion of said Council, a public health emergency exists, the Commissioner of Health may enforce the rules and regulations of the State Department of Health within the territorial jurisdiction of such local health authorities, and for that purpose shall have, and may exercise all the powers given by statutes to local health authorities; all expenses so incurred to be a charge against the cities and towns concerned.

Section 7. Towns and cities may cooperate for promotion of the public health, either by special vote or by vote of their respective boards of health. They may participate in the employment of trained health officers or other agents, and in the installation and maintenance of a common laboratory or other equipment. Funds may be appropriated and disbursed for this purpose either by a special vote of a city or town, or by vote of a board of health of a city or town from appropriations or other funds at its disposal. Whenever two or more towns shall thus combine or cooperate for more efficient health service, and shall appropriate a sum or sums of money for such joint or cooperative action, a sum equal to two-fifths of the total amount contributed by the cooperating towns shall be paid over and added thereto from the Treasury of the Commonwealth; provided, that the general plan of cooperation, as well as the principal health officer, executive agent, or laboratory director employed by the cooperating towns, shall have been approved annually by the Public Health Council; and *provided, further*, that no sum so paid to any such group of cooperating towns shall exceed $1000, in any one year.

Section 8. An annual conference of health officers shall be held under the supervision of the Commissioner of Health, and necessary expenses of health officers attending said sanitary conference shall be paid by individual boards of health respectively, or by the selectmen acting as boards of health.

Section 9. For carrying out the purposes of this act there shall be appropriated for the purposes of the State Department of Health, over and above the amount already appropriated for the State Board of Health for the year 1914, the sum of

Section 10. All acts and parts of acts inconsistent with this act are hereby repealed.

AN ACT TO REORGANIZE THE MASSACHUSETTS STATE BOARD OF HEALTH.

In response to an invitation extended by the Massachusetts Medical Society, ninety physicians of the Massachusetts Medical Society, the Homeopathic Medical Society and the Massachusetts Eclectic Medical Society, met at the Boston Medical Library, May 15, 1914, at 3 p.m., to discuss the act to reorganize the Massachusetts State Board of Health (House No. 2590) introduced into the Legislature May 12. Representatives from at least ten counties of the state were present.

The meeting organized by the election of Dr. W. P. Bowers of Clinton, chairman, and Dr. W. L. Burrage of Boston, secretary.

Governor Walsh explained the provisions of the act at length, and Dr. M. J. Rosenau, a member of the State Board of Health, who drafted the bill, sketched its chief purposes. Twelve different physicians present took part in the discussion and the Governor and Dr. E. H. Bigelow and Dr. Rosenau answered questions. Dr. Trowbridge of Worcester proposed the following amendment to Section 5, line 3: Insert after the word *officer*, "Who shall be a physician in good standing." On motion of Dr. Duggan of Worcester it was *Voted:* That the meeting indorses the recommendations and the bill of Governor Walsh as to the creation of a State Department of Health (House Bill No. 2590) with the amendment above noted. The vote was unanimous.

Adjourned at 4.53 p.m.

WALTER L. BURRAGE,
Secretary of the Meeting.

ADDRESS TO DR. WALCOTT.

The following is the text of the address presented to Dr. Walcott on his retirement from the State Board of Health.

To Henry P. Walcott, M.D., LL.D., Chairman, Massachusetts State Board of Health, from Twenty-two Hundred Members of the Medical Profession of the State, Greeting:

Sir: On the 19th day of May, 1914, your term as a member of the State Board of Health ends, and we understand you are not a candidate for reappointment.

Such an occasion cannot be allowed to pass unnoticed, at least by those citizens who as a class should be most competent to gauge the value of such services to the State as yours have been.

The best appraisal of those services is the mention of some of them, with a brief statement of your relations to the Board.

Your connection with the Board began in 1880, 33 years ago, when, after ten years of independent existence, it had been merged with the conjoined Board of Lunacy and Charity, and you were unanimously elected its Health Officer. At this time, you served on a commission for the sanitary im-

provement of the Blackstone river, a precursor of your subsequent labors on similar problems.

In 1886, by an act of the legislature, the Board of Health once more entered upon an independent existence. You were appointed a member for a seven years' term by Governor Robinson, a Republican, with the advice and consent of the senate, and became the chairman. You have since been reappointed three times for terms of seven years: once by Governor Russell, a Democrat, in 1893; once by Governor Crane, Republican, in 1900; and once by Governor Guild, Republican, in 1907. Since 1886, you have always continued as chairman of the Board.

Early in 1894, you began to consider the advisability of establishing a laboratory for the free production and distribution of diphtheria antitoxin; and such curative serum was actually distributed early in 1895, being the first so distributed in any state. This was made possible through the cooperation of Harvard University, secured by your influence, at the Bussey Institution, and was carried on for nine years—during this time as well as later under the personal direction of Dr. Theobald Smith—until 1903, when the legislature enacted a law authorizing the State Board of Health to produce and distribute antitoxin and vaccine virus. Again through your influence, a laboratory was built on the grounds of the Bussey Institution where the preparation of antitoxin and animal vaccine was carried on together.

Within the last four years, you have served as chairman of two State Commissions appointed to consider various important tuberculosis problems: one in 1910, and one in 1912. Reports were made to the legislature and printed as public documents.

It is impossible to separate your work in connection with the Board of Health from that in connection with the North and South Metropolitan Sewerage Systems, the Charles River Valley System, the Charles River estuary improvement, the Metropolitan Water Supply, and numerous other similar problems of perhaps secondary importance, such as the improvement of the Neponset River Valley, of the Concord and Sudbury Rivers, of the sanitary conditions as respect water supply, sewerage and sewage disposal of many other cities and towns which have been devised by the committee on water supply and sewerage of the Board of Health, of which Mr. Hiram F. Mills is chairman, and carried out in connection with its recommendations under your chairmanship of the Board.

Since the reëstablishment of the State Board of Health in 1886, under your chairmanship, it has been the custom of the legislature to refer all important sanitary questions to that Board for investigation and advice, instead of creating special commissions, as obtains in many states. This custom, under your wise administration, has doubtless saved much money to the State and, at the same time, secured sanitary improvements recognized in all civilized countries as the best of their class.

The investigations and recommendations of the Board have commended themselves to the legislature and in general have been carried out ultimately as presented.

From 1886 to the present time, you have been constantly and steadfastly facing these great and grave problems. Since 1895, when the State Board of Health made its report to the legislature, presenting a plan for the water supply of the City of Boston and the surrounding cities and towns, have been added to your responsibilities those of a commissionership on the Metropolitan Water Board. You have borne the responsibilities both of recommendation and of execution.

You have succeeded on the Board of Health such men as Henry I. Bowditch, George S. Derby and Charles F. Folsom, whose services to State medicine were widely known and recognized, and honorable to Massachusetts.

You have met the responsibilities then assumed with such wisdom, discretion and rare modesty, as to make the task of your successor who would uphold the standards bequeathed to him a difficult one indeed.

Correspondence.

ANOTHER LESSON IN ANTI-VACCINATION.

BOSTON, May 11, 1914.

Mr. Editor: The recent experience of Niagara Falls, a tourist city of about 35,000 inhabitants, is interesting as showing the harm that a persistent, fanatical anti-vaccinationist is capable of doing even in these enlightened days. Being refused admission to the local press, this physician has been publishing and distributing pamphlets decrying vaccination for years in the untruthful, exaggerated manner peculiar to this cult. About 90 per cent. of the inhabitants had become lukewarm toward vaccination and about 60 per cent. were distinctly opposed to it. Now for the results.

In 1912 smallpox made its appearance in the city in a sporadic form. Little attention was paid to the situation until late in 1913, when the epidemic blazed up and became so serious that Buffalo and other adjoining towns began to interfere. Business was affected, which is one of the most potent factors in these conditions.

As the local authorities could not or would not take the necessary measures to stop the epidemic, the Health Commissioner of the state, Dr. Hermann M. Biggs, was called upon to take a hand in the situation. The authorities were given to understand that unless they took the usual means immediately to stamp out the disease, the city would be placed under quarantine. The commissioners' suggestions were accepted and carried out. The epidemic was under control in a short time.

During 1913 the cities of New York, Rochester and Buffalo, with 6,000,000 people had 39 cases of smallpox. Niagara Falls had 196. The law excluding unvaccinated children from the public schools is rigidly enforced in the three cities above noted. The aforesaid anti-vaccinationist had made his brags that Niagara Falls had a larger percentage of unvaccinated citizens than any other city in the country. The result of this epidemic would seem to justfy his claim.

When the city took hold of the situation in an intelligent manner, the people tumbled over each other to get vaccinated. About 22,000 were vaccinated in a short time. Churches, theatres, libraries and all other places of public assemblage were closed. The schools were not closed, but all unvaccinated children were excluded. Inspectors were sent to every house to ferret out concealed cases. The sick were isolated. The usual results of the proper management of these epidemics were soon in evidence and the danger was over. The epidemic was easily preventable. The city has only itself to blame for the prevalence of the scourge. It is to be hoped that the lesson will not be forgotten in a hurry. Massachusetts may well take warning from this fresh example of neglecting plain and safe measures of protection against this loathsome disease.

Very truly yours,

GEORGE W. GAY, M.D.

Address.

IN MEMORY OF SILAS WEIR MITCHELL, M.D., LL.D.*

BORN FEB. 14, 1829; DIED JANUARY 4, 1914.

BY JAMES J. PUTNAM, M.D.,

Professor of Diseases of the Nervous System, Emeritus, Harvard University.

IT is not my purpose to attempt tonight an adequate characterization of the personal qualities or of the scientific and literary standing of the late Dr. S. Weir Mitchell. All that I propose to do is to offer, in the name of this society, some slight tribute of affection and respect.

No one can doubt that Dr. Mitchell will be remembered as among the foremost of American physicians, and as taking a high place among American literary men. The testimony of his innumerable and deeply grateful patients and of the vast circle of his professional friends, the long list of his medical and scientific publications, the still longer list of his literary works, and the many honorable tokens of appreciation bestowed on him by American and foreign societies and institutions, place this statement beyond question. He felt also the obligations entailed by his powers and opportunities, and kept his torches burning until the very last, so much so that the issue of *Science* published on December 12, 1913, only three weeks before his death, contained a memoir by him of his friend, the late Dr. John Shaw Billings. So predominantly characteristic was this endurance, until the last, of his vivacity, his eagerness and his activity, that one saw at once, in him, a man of the type made deathless by Tennyson's "Ulysses," longing, even in his closing years, to re-live the days that had been so full of joys and combats among his peers, and seeking to the very last new friendships and new worlds.

". . . I will drink
Life to the lees; all times I have enjoyed
Greatly, have suffered greatly, both with those
That loved me and alone; . . .
. . . . .
"For always roaming with a hungry heart
Much have I seen and known; cities of men
And manners, climates, councils, governments,
Myself not least, but honour'd of them all.
. . . . .
"I am a part of all that I have seen;
. . . . .
"Tho' much is taken, much abides; and tho'
We are not now that strength which in old days
Moved earth and heaven; that which we are, we are,
One equal temper of heroic hearts
Made weak by time and fate, but strong in will
To strive, to seek, to find, and not to yield."

* Read before the Boston Society of Medical Improvement, March 23, 1914.

But if Dr. Mitchell was distinguished for his talents, his industry, and his achievements, it is equally true of him that he was a warm-hearted lover of mankind both in a narrower and a broader sense. To all who cared for them he was generous of his time, his interest, and his affection, recalling, in this respect, his close friend, Sir William Osler. Such failings as he had were of a very human sort, tending to intensify the sense of relationship to others, and inducing him to make himself felt by them as a warm and living person. These genuinely human interests may have furnished one deep root for his strongly religious tendencies, and for the courtliness of manner which contributed to his charm. They also explain Sir William Osler's saying: "Of no man I have known are Walter Savage Landor's words more true, 'I have warmed both hands at the fire of life.'"

Endowed with an affectionate and highly social temperament, a brilliant mind and quick wit, he went on through life continually forming new friendships of the best sorts, as with such men as Phillips Brooks, and drinking forever at the self-renewing fountains of youth. Some men seem built to run smoothly in some one groove alone, and are driven by their destinies to become, this one a poet, that a man of science, and so on. But Dr. Mitchell's main desire, I think, was not so much to become eminent in any special lines as to leave no well-marked line of human interest untouched. The great variety of the subjects dealt with in his stories and his poems, the great variety—all things considered—of his scientific attainments, the great variety of temperaments to be found among those who could call themselves his friends, illustrate this point.

To Dr. Mitchell's friendliness I can bear personal witness. For though he was at the top of the ladder when I was at the foot, he went out of his way, at that period, on several occasions, to receive me as an equal and friend. Well do I remember dining at his hospitable table while still in the greenness of relative youth, and eating there the fatted terrapin, fatted, as I remember, in his own cellar, and served up with as good a sauce as any self-respecting terrapin could desire. My first acquaintance with him was, however, of still earlier date, for it is well-nigh forty years ago that he came as a consultant to visit a life-long invalid who had the distinguished honor of being almost my first patient. I can recall with perfect distinctness his pleasant manner on that occasion, and the dew of soothing encouragement which his visit left behind for both of us.

It is with great pleasure also that I recall a visit made in company with Dr. Mitchell to the Orthopedic Infirmary, which, if I am right, he transformed from a no doubt useful, but somewhat unknown, institution of one kind into a real scientific centre of quite a different kind, its old name, however, being retained. It was

here that many of his scientific researches on a clinical basis and many of his therapeutic studies were instituted, with admirable results.

These reminiscences of my youth may be capped by a story which he told me of his own, and which I re-tell with the greater pleasure that it seems to me to describe certain of his strongest traits. He had just become, he said, the assistant of his father, the eminent Dr. John K. Mitchell of Philadelphia, and was left by the latter, who had gone on a vacation, to hold the fort during his absence, with instructions to keep the practice going, and the patients alive, if possible, until his father should return. Dr. Weir Mitchell was then the rawest of young doctors, but already conscious of that undying well-spring of courage and resourcefulness which remained with him through life. Who should the first patient be with whom he had to deal, during this important interregnum, but a gentleman with an inveterate psoriasis, who had traveled the world over in the elusive search for health, and had come at last, as Naaman came to Elisha, to seek the senior Dr. Mitchell! What should be done? The improbability of a cure simply by repetition of old methods stared Dr. Mitchell in the face, and the fashion of that particular period was not favorable to the recommendation of dipping just seven times in Jordan. But his courage and his inventive genius stood him in good stead. He put the patient to bed, under the care of a trained nurse, and bled him copiously, at first daily, then less often, hoping almost against hope that the disease would admit itself starved out before the patient should succumb. Not without grave anxiety he watched the distinguished invalid growing weaker day by day. But at last, when even his hopefulness threatened to give way, the spots began to fade, and finally disappeared. Then came the fattening-up, and after this had reached the proper point he sent his patient off, well satisfied with the treatment he had had.

It is easy to see indications that these qualities of resourcefulness and daring played a part in Dr. Mitchell's career on many an occasion, and to imagine their influence where it was not visible. One might have thought that they would have tempted him to surgery. It is, however, an interesting fact that although at the request of Surgeon-General Hammond, and with the valuable aid of Drs. Morehouse and Keen, he organized an excellent hospital during the Civil War, where he gathered the large material to be used later for the classic work (by Mitchell, Morehouse and Keen) on "Gunshot Wounds and Other Injuries of the Nerves," and although he actually tried surgery, yet he found it to be distasteful, and soon abandoned it. My warrant for this statement is an interesting letter very kindly written to me by Dr. John K. Mitchell, in which he says that Dr. Weir Mitchell's father at first tried to dissuade his son from studying medicine at all, "as not being of the disposition or having the studious and persevering kind of character that would make him successful in it." Finding him determined to persist, however, he urged him to take up surgery by preference, as being better paid than medicine, and more in the way of development at that period, which was about 1850.

> "In consequence, in spite of a great distaste for surgical operations and even for bloodshed, my father worked at it, and worked in Paris as well as here, and even for a while performed operations. He saw the end of operations without anesthetics and the beginning of operations with anesthetics, but he soon proved to himself and convinced his father that he was not likely to make a surgeon."[1]

The hospital, it should be said, was planned for soldiers suffering from nervous diseases. But its scope

> "was soon enlarged to include men suffering from injuries of the nerves. Before long it was found necessary to build a new hospital with accommodations for 400 patients. Here a vast number of cases representing almost every conceivable type of obscure nervous disease was received. Few persons have at any time had such a field for the study of these maladies, and Dr. Mitchell and his colleagues made full use of their opportunities."[2]

The book on injuries of the nerves, written in 1864, has always seemed to me a contribution of high merit. It was no mere restatement of the views of others, but embodied personal observations giving evidence of keenness and originality. This experience in the army secured to Dr. Mitchell the opportunity to obtain consultations in neurological cases and led him to devote himself for the most part to the study of that subject, which held his interest until his death.

The subject of Dr. Mitchell's medical and scientific labors is soon to be reviewed by one well qualified to do the subject justice, and cannot be discussed here in detail. To those whose memory stretches back so far, the very titles of some of his original communications, as "Reflex Pain," and "Erythromelalgia," arouse stimulating recollections.

It was this same self-confidence to which I already have referred that led Dr. Mitchell, about fifteeen years ago, to deliver his bold broadside against the system then prevalent in hospitals for the insane, under which the superintendents had become to a great extent mere administrators, neither doing nor expected to do much of anything in the way of scientific work. The criticisms thrown out in this address

[1] Letter from Dr. J. K. Mitchell.
[2] *Brit. Med. Jour.*, January 10, 1914.

may have been felt as unjust by this person or by that. But the stand taken went a long way toward modifying for the better a custom which had become very much of a reproach, and made it easier for the superintendents, whose task had truly been a hard one, to demand laboratories and to set the machinery of research in operation.

I will add another trifling, but amusing character-story, given me by Dr. F. C. Shattuck, in which similar traits appear. Dr. Mitchell was, it seems, just leaving Milan after a temporary visit, when a gentleman came up to him in the hotel, asking if this was Dr. Weir Mitchell of Philadelphia and saying that he greatly wished to consult him, as he was a serious sufferer from insomnia. Dr. Mitchell declared that the carriage was at the door, and that his departure could not be delayed. But while talking with the would-be patient he noticed a brown stain at one corner of his mouth, and observed the ends of a number of big cigars sticking out of his vest pocket. Taking advantage of these hints he ventured the opinion that his insomnia was due to too much tobacco, adding the guess that he both smoked and chewed heavily. The astonished patient admitted the soft impeachment, and wrote to him a month later that his opinion and the treatment based upon it had been poductive of excellent results.

In some respects the mental attributes of the scientific student were as prominent in Dr. Mitchell as his genius for therapeutics; nor was he less competent in literary research. His interest in problems of physiology never slept, and the questions that presented themselves in the course of his clinical studies provided an ample field for its operation. One may get a good idea of the range of these studies from reading the Presidential Address before the American Neurological Association, delivered in 1909, where Dr. Mitchell runs over and in a measure sums up his views on some of the topics that had been before him earlier. It was, however, his elaborate studies on rattlesnake poisoning that mainly won for him praise and fame as a student of physiology. His first contribution on this subject was published in 1860, the last in 1886, both being brought out by the Smithsonian Institute. I believe it is true, however, that his interest in the matter was a continuous one, and if I am not mistaken, he made a visit to India in prosecution of his researches. Dr. John K. Mitchell writes to me, "I think the interest in snake poisoning began with some physiological investigations which he and William A. Hammond made together in respect to two South American poisons—corroval and vao,—both of which were said to have serpent venom mixed with them."

Toward the close of this investigation he sent to Dr. Oliver Wendell Holmes, who had long been a close friend, the skin of one of his largest reptiles, and received in return some witty acknowledgments, one of which I quote:

March 1, 1883.

My dear Dr. Mitchell,—

I am reminded of Pope's line:—

"Pleased with a—rattler—tickled, etc."

I don't think I have it quite right, but anyhow I am both pleased and tickled with my rattler's integument. It is magnificent,—not Tofana or Madame de Brinvilliers in all her glory of silks and satins, was clad like one of these. But what a parlous worm it was, to be sure! I didn't know that pizon sarpents ever grew so big as that. He must have shed venom as a milch cow does her amiable secretion. I have got him hung up on my revolver (book-shelves, that is), and he hides a library of volumes. And when he rattled, how he must have waked the slumbering watchmen, if any such were within range! I should greatly enjoy a short biography of this individual specimen of a race which owes so much to your pious labors.

Well, well,—asps and vipers and copperheads, and cobras and rattle snakes of reasonable dimensions I know, but a crotalus with the length and circumference of a boa-constrictor is a new acquaintance, whose *bark*, if I may so call his integument, is much more welcome than his bite would be.

Always, and this time thankfully, yours,

Oliver Wendell Holmes.

In 1906 Dr. Mitchell read, also before the Association of American Physicians,[1] the report of a number of interesting experiments of poisoning by the mescal button, which he said produced optical phenomena suggesting those occurring in migraine.

Psychologically speaking, there is considerable similarity, after all, between the tendencies that lead men to show energy and skill in research of scientific sorts, and those that draw them into investigations in literary fields. These latter fields were wandered over widely by Dr. Mitchell, and my attention has been called, in illustration, to the fact that he did at one time an excellent piece of work in retouching with new illumination the time-worn topic of the great Harvey, and that he succeeded in finding two hitherto unpublished Harvey letters.

As a practising physician Dr. Mitchell found himself constantly in situations where his interest in his fellow-men, harnessed to his courage, his originality and his scientific knowledge, made a strong team. We all remember the stirring breeze, one might almost say Northwester, excited by the publication of his series of little books beginning with "Wear and Tear" and "Rest in the Treatment of Disease," published in 1873 and 1875, respectively, and reaching its climax with "Fat and Blood," in 1877.

[1] Transactions, 1906.

His interest in these matters did not then cease, however, and as late as 1908 he published what may be called the last of the series, on "Rest Treatment and Psychic Medicine."

No one who recalls the earlier booklets of this series and was a living witness of the effect that they produced on the minds of the many toilers with the problem of neurasthenia, can fail to remember how strikingly the lesson was impressed, that when it comes to actually curing patients, the value of a certain amount of very important theoretical information pales into insignificance by the side of a system well worked out in its details. Rest is good, and food is good. But it is by no means always clear how to make these benefits available. Something else is needed. We know now, as we did not know in those days, when suggestion had not been adequately studied, that one or both of two influences must be present if one would really cure a nervous patient. Either he must be made to believe in the doctor, or he must be trained—slowly and painfully, if need be—to believe thoroughly in himself. Dr. Mitchell really used both of these means; for therapeutist of high order though he was, he fully appreciated, too, the value of independence, and sought faithfully to encourage it among his patients. Nevertheless, it seems clear that what his instinct felt to be the main need of the hour was that each invalid should have demonstrated to him, by the logic of facts, that his indigestion was not invincible, but that his physician's command of the situation was. What hungry person, even though a neurasthenic, could fail to welcome, without complaint of indigestion, the slender portions of skimmed milk with which the treatment started in? Or what fatigue-fearing patient could venture to speak longer of fatigue when the only effort allowed to him was that of brushing his own teeth?

Sir William Osler, in a letter to the *British Medical Journal* concerning Dr. Mitchell, writes interestingly of the clinical emergency which was the occasion of the theory of the rest cure. In Dr. Mitchell's own graphic terms he gives the history of the patient, a Mrs. S. of Bangor, Maine, telling of her school life, her marriage and nervous breakdown, and of the conflicting thoughts that passed through Dr. Mitchell's mind as he stood at the foot of her bed, doubtful what course he should pursue. The story ends with the statement that the patient was sent back to Bangor perfectly well, that she afterwards bore many children, and had been the soul of many enterprises in her native town. Dr. John K. Mitchell, in the kind letter above alluded to, tells me that this lady from Bangor, who was treated in February, March, and April, 1874, has recently written him a pleasant note accompanied with a portrait of herself.

Dr. Mitchell never taught in either of the great medical schools of Philadelphia, but he did excellent work for many years as trustee of the Carnegie Institute, and performed conspicuous service in securing the endowment for the splendid building of the College of Physicians in Philadelphia, now an important medical centre, containing a collection of books equalled, I believe, only by the Surgeon-General's Library at Washington. In this latter undertaking, as in so many others, his co-worker was the genial, single-minded, and public-spirited Dr. William W. Keen, who, from being his valued assistant in the army, became his life-long friend.

As a literary man, Dr. Mitchell has a large number of admirers, as we all know, and there are doubtless many members of this society who would be far better able to give a just estimate of his work than I can do. His output of stories and poems was very large, and I can aver that many of the poems are full of interest and charm. Those who are interested will find some account of Dr. Mitchell as poet in an article written by Robert Haven Schauffler and published in the *Century* for December. The poems dealt with there are finer specimens of his work than those which I shall quote, but in glancing over one small volume I was much struck with his power of endowing with the delicacy of his own feeling the sights and sounds of nature of which he was so fond. How the soul of the wave and fog and the soul of the man seem to interpenetrate, for example, in these lines:

STORM-WAVES AND FOG ON DORR'S POINT, BAR HARBOR.

The fog's gray curtain round me draws,
And leaves no world to me
Save this swift drama of the stirred
And restless sea.

Forth of the shrouding fog they roll,
As from a viewless world,
Leap, spectral white, and, pausing, break,
In thunder hurled.

Ever they climb and cling anew,
Slide from the smooth rock wall,
With thin white fingers grip the weeds
And seaward crawl.

In rhythmic rote o'er shivering sands
They glide adown the shore
With murmurous whispering of "Hush!"
And then no more.

Equally sympathetic is his appreciation of the harsh and tuneless but thrilling note of the sea-gull, as shown by the following verses selected from a much longer poem:

The woods are full of merry minstrelsy;
Glad are the hedges with the notes of spring;
But o'er the sad and uncompanioned sea
No love-born voices ring.

Thou silent raider of the abounding sea,
Intent and resolute, ah, who may guess
What primal notes of gladness thou hast lost
In this vast loneliness!

Where bides thy mate? On some lorn ocean rock
Seaward she watches. Hark! the one shrill cry,
Strident and harsh, across the wave shall be
Her welcome—thy reply.

Home! for the night wind signals, "Get thee home";
Home, hardy admiral of the rolling deep;
Home from the foray! Home! That silenced song
Love's endless echoes keep.

For more than one cause then, Dr. Mitchell, whose achievements kept him in the forefront of a large band of distinguished men throughout a big and brimming half century, and made him almost as well known as the city with which he was so intimately identified, deserves to be remembered as a great man, and one filled abundantly with the wine of the intellect and of the spirit. Always eager, always virtually working even when nominally resting, warmly sympathetic, and in the best sense self-forgetting, his eighty-five laborious years were spent in the courageous service of the truth as he saw it, and in the constant presence of ideals and visions, of which his books and poems, his estimate of Phillips Brooks and of his own invalid sister, and the admiring voices of his friends, give willing evidence. Very different though his life was, in its external features, from that of the Canadian poet, William Henry Drummond, in memory of whom he wrote some charming and warm-hearted lines, published in 1910, these lines well describe a side of himself that was perhaps not the one most widely known, and with them this slight sketch may close:

IN MEMORY OF WILLIAM HENRY DRUMMOND.

Peace to his poet soul. Full well he knew
To sing for those who know not how to praise
The woodsman's life, the farmer's patient toil,
The peaceful drama of laborious days.

He made his own the thoughts of simple men,
And with the touch that makes the world akin,
A welcome guest of lonely cabin homes,
Found, too, no heart he could not enter in.

The toil-worn doctor, women, children, men,
The humble heroes of the lumber drives,
Love, laugh, or weep along his peopled verse,
Blithe mid the pathos of their meagre lives.

While thus the poet-love interpreted,
He left us pictures no one may forget—
Courteau, Baptiste, Camille mon frère, and, best,
The good, brave curè, he of Calumette.

With nature as with man at home, he loved
The silent forest and the birches' flight
Down the white peril of the rapids' rush,
And the cold glamour of the Northern night.

Some mystery of genius haunts his page,
Some wonder-secret of the poet's spell
Died with this master of the peasant thought.
Peace to this Northland singer, and farewell!

[Since this hasty sketch was written, Dr. Mitchell's exceedingly interesting Chicago address has been published (*Journal of the American Medical Association*, May 9, 1914), telling of the work of the Medical Department of the United States Army during the Civil War, and something more of his own labors and those of his personal colleagues than was within my knowledge. In many respects this warm and able essay, written hardly more than a year before Dr. Mitchell's death, helps to place vividly before us the personality of its intensely human, life- and labor-loving writer.]

REMARKS ON DIAGNOSIS AND TREATMENT OF DISEASE OF THE STOMACH.*

BY FRANKLIN W. WHITE, M.D., BOSTON,

Instructor in Medicine, Harvard University; Assistant Visiting Physician, Boston City Hospital.

I WILL speak first of some new methods of diagnosis and some old methods which have new values. The history has always been the most important factor in diagnosis and still is, in spite of the development of new methods. The history holds first place and the x-ray and the chemical tests divide the second and third places between them. No one symptom is distinctive however. Moynihan's statement, that "hyperacidity is ulcer" is not strictly true. Hyperacidity is one of the most common conditions of the stomach, due to a variety of causes and as seen in our Out-Patient Department and in private work most cases recover under careful treatment and show no signs of ulcer. There is always a small group which do not yield to medical treatment and which are sent to the surgeon. These are the most severe and trying cases and the only ones which the surgeon ordinarily sees. Here the per cent. of ulcer is high and prompts the statement which Moynihan has made. We must remember, however, that cases are carefully sifted before reaching the surgeon and surgical statistics are only of value for the class of cases seen by the surgeon.

TESTS OF SECRETION.

The stomach tube still holds its own as a means of testing gastric secretion. The Desmoid test, Einhorn's bead test, the string test of secretion, are comparatively unreliable and are little used. Chemical tests were formerly far too highly valued and now have been put in their proper place. The old days when a physician sent a specimen of stomach contents to a laboratory or consultant for complete diagnosis have passed, never to return. We are no more able to make a complete diagnosis from the stomach contents *alone* than we are from the examination of the urine. The tests have much value and we could not do without them, but they rarely make an in-

* Read at the Boston City Hospital, Clinical Meeting, Feb. 12, 1914.

dependent diagnosis and in some cases like duodenal ulcer they show surprisingly little.

There has been little change in the tests used in the last ten or fifteen years with the single exception of tests for blood. Here we may say that too much activity has been shown. Starting with the old Guaiac test, new tests have been brought out each more delicate than the last, such as the Benzidin, Phenolphthalein and Toluidin tests. Extreme delicacy is not desirable in these blood tests, any more than in a test for lactic acid or for mucus. It is possible to find blood so frequently with a very delicate test that it has no value in diagnosis. Blood tests are used everywhere nowadays to detect and rule out gastro intestinal ulceration and the ideal test should be simple and easy and not too delicate or too coarse.

In my opinion the ordinary Guaiac test is a rough test, not delicate enough for clinical purposes. Since it will not show blood in the feces with an ordinary meat diet, how can we expect it to show traces of blood which come from an ulcer? A recent report from the Mayo Clinic shows that the Guaiac test did not detect blood in the stomach contents in more than half the cases of gastric cancer In my opinion the Benzidin test is the best test. It is recommended by all the recent text books; I have used it for years and found it simpler and easier and far more reliable than the Guaiac test for detecting traces of blood. Pure reagents clean glassware, and a proper technique are necessary for satisfactory results.

This test like most others which are used for blood can be made too delicate for clinical work. I think Schlesinger and Holst's modification of the test is the best, using two drops of gastric contents or two drops of a mixture of feces and water for making the test. The technique has been fully described by the author in previous papers.[1]

This test has been slow in reaching Boston for some reason, but I am glad to see it in routine use here at the hospital at the present time. I have given both the Phenolphthalein and Toluidin tests a thorough trial and find them less satisfactory for clinical work.

TESTS OF MOTILITY.

This is the most important gastric function or at least the one which makes the most trouble if deranged. The stomach tube has been our reliance in making this test by finding fasting residue in the morning, of a test supper given 12 hours before, but now the tube comes in for its share of criticism. The x-ray shows that the tube may coil up in the stomach and avoid the residue and make the test useless and misleading; in other words, the radiologist says,[2] "When we pass the tube in the morning to recover fasting contents and find none, we do not know whether none is there or whether we have simply missed it." Such a poor result may occur without doubt, but I believe it may be avoided by proper technique. In the first place the stomach tube should be a straight one, kept straight by being hung up by the tail. It is often kept coiled by the maker and often kept coiled by the physician who uses it. This is a mistake. The coiled tube is much more likely to kink and curl up in the stomach while the straight tube has little tendency to do so. In the second place it is very desirable to use gentle aspiration in obtaining fasting contents and not to trust to syphonage or expression through the tube. It is obviously impossible to start a syphon with only a few teaspoons of stomach contents. A soft Pollitzer bag of the type made by the Davol Rubber Co., easily detachable is the best aspirator and will, if the stomach tube is moved back and forth during aspiration, recover even small traces of fasting residue. Finally if the stomach is washed out at the end of this process with a bulb full of water I think we are practically sure to detect traces of food if they are present in the stomach. This test of the stomach motility with the tube is in my opinion a very reliable one and not easily replaced by any other method.

Tests of motility made with the stomach tube and by the x-ray after a bismuth meal are not exactly comparable. They run parallel to one another in a general way, but the natural meal may leave the stomach either earlier or later than the bismuth meal. The cause for this we do not know. It may be that sometimes the bismuth acts as a foreign body and hastens emptying of the stomach or that in other cases it sticks to the wall and remains longer than food. The time of passage of natural meals is what we really wish to know.

In diagnosis of the motor power of the stomach the tests probably have equal value. The difference is that for many years, thousands of men all over the world have used the tube test. We have had enormous experience with it and know how to interpret its results; we have had much less experience with the x-ray method at the present time.

THE X-RAY.

The x-ray has been a very great help in diagnosis of diseases of the stomach. It shows the position, size and shape of the stomach as no other method will do, and most important of all it shows constant deformities in outline, due to ulcer, tumor or adhesions. It has been a great help in separating the medical from the surgical stomach cases. So much new data about the stomach has been obtained by the x-ray that at present it is in a somewhat undigested state and rather confusing. Some men use chiefly plates and give us one set of results, other men use chiefly the screen and give another set of results. The bismuth meals used are quite different in both

size and quantity. Different amounts and kinds of foods are used and different salts of bismuth and barium so that the results obtained by different men are not comparable. It seems as if a standard bismuth meal just as we have a standard Ewald-Boas test breakfast would be a great advantage.

In addition the x-ray men are not entirely in accord among themselves on important points of technique and diagnosis. To speak of one or two specific instances: Some men lay great stress on the importance of diagnosing a six hour bismuth residue in the stomach. Holzknecht has developed an elaborate scheme based on such observations as, "Atony never gives a six hour residue," "Gastric ulcer always gives a six hour residue." This is too dogmatic and is not true with the bismuth meals generally used. Atony may give an eight or ten hour residue and in fully half the gastric ulcers the stomach may empty in six hours. Other x-ray men consider a six hour residue the least important factor in diagnosis, merely a symptom depending on a great variety of causes.

Spasm of portions of the stomach has been a great source of error in diagnosis. They come from too many causes outside the stomach such as the gall-bladder, appendix, renal calculus, tabes and drugs, to be of much value in the diagnosis of gastric ulcer.

The x-ray appears to be somewhat in the position of the chemical tests ten or fifteen years ago, when it was said "lactic acid means cancer," "free HCl and a trace of blood means ulcer." These things have not proved to be true; there is a danger in being too dogmatic with too little experience.

On the other hand direct evidence of constant deformities has great value, as for example in duodenal ulcer. In a modest series of private cases in which an x-ray diagnosis of duodenal ulcer was made, the cases which came to operation proved the x-ray diagnosis to be correct in every instance. (I must admit that all these cases were typical and a definite diagnosis was made by older methods before sending them to the radiologist for confirmation.) Whether the reverse is true, or not, that is, whether a negative x-ray examination means no ulcer, I cannot say. My experience does not go so far. It is not easy to prove since the cases are less likely to be operated upon.

With adhesions about the pylorus it does not seem fair to expect the x-ray to show the cause, such as a previous ulcer, or gall bladder inflammation, but simply to show their presence by the deformity they produce, and let other clinical methods decide about their origin.

There is some doubt whether or not the x-ray can make a diagnosis of cancer of the stomach earlier than other methods, except in an occasional case. It certainly seems possible that it may detect mechanical changes in the wall of the stomach due to cancer of the fundus, or away from the pylorus, before changes in secretion have occurred or any considerable disturbance of the general health. I am sorry to say that I have had little experience with early cancer as most of the cases that are sent to me for diagnosis have already passed the early stage.

The x-ray is not an independent method of diagnosis. It should be used with the history and the chemical tests to get the best results in difficult cases. One x-ray man of this city said to me recently, "I have to urge men to make the chemical tests in the stomach cases which they send to me for diagnosis. They apparently feel that if an x-ray examination is made, nothing more is necessary." This attitude is wrong and shows that the pendulum is swinging too far toward the new method.

SYPHILIS.

The relation of syphilis to ulcer of the stomach is important. Syphilis has been always considered one of the rarest diseases of the stomach. We may have to change our opinion about this. The Wassermann reaction has detected an enormous amount of latent syphilis in heart, vascular and renal cases and may perhaps do the same with regard to the stomach. My attention was called to the importance of syphilis by having several successive cases of peptic ulcer this fall with a triple positive Wassermann reaction. This may be simply a coincidence, but it may be more than this. Any patient who has syphilis may develop a peptic ulcer as an independent disease, but it is also possible that some of our chronic ulcers are syphilitic in origin. Two of the patients referred to were given anti-syphilitic treatment and treatment of the stomach combined and made an excellent recovery. The cases are too recent to know about recurrence and are not conclusive.

It would be much more definite if we find we can take such cases which have resisted ordinary thorough medical treatment and promptly cure them by giving the ulcer anti-syphilitic treatment. I think the subject is so important that it is worth while to try the Wassermann reaction in every chronic peptic ulcer. We may save some from the necessity of operation. I can see no reason to expect the x-ray to help us to distinguish a syphilitic ulcer from other ulcers of the stomach.

CANCER FROM ULCER.

The question of the development of cancer from chronic ulcer of the stomach is important and there is much conflicting opinion about its frequency. The old figures gave us six or seven per cent. of cancer developing from previous ulcer. Moynihan and the Mayo clinic place the figures about ten times as high, namely they believe that 60 to 70% of gastric cancer de-

velops from previous ulcer. It is difficult to reconcile these high figures with our clinical experience. I recently looked over my records of 100 cases of cancer for evidence on this point and found that a large majority of the cancer cases had a short history of digestive trouble; that less than one quarter of the cases had had any previous digestive trouble, and that less than one-tenth presented real evidence of preceding ulcer. Furthermore in a small group of ulcer cases followed for years without operation, the development of cancer is a great rarity.

While this clinical evidence is not absolutely conclusive it leads me to believe that the above figures, 60 to 70% are really far too high to represent the average run of cases of cancer of the stomach; that while they may be true for the carefully sifted and selected material of these surgical clinics, they do not represent the conditions met with in every day practice. My own impression is that less than one quarter of the cancers of the stomach develop from previous ulcer and perhaps the actual figures are much lower than this. Bearing these things in mind it certainly is not desirable to send every ulcer case to the surgeon as soon as the diagnosis is made, neither is it desirable for the surgeon to resect every accessible ulcer of the stomach.

TREATMENT.

I will speak briefly of a few of the newer drugs. Hydrogen peroxide, used internally by Petri in 1908, has a great power of lowering the acid of the stomach. This was first thought due to depression of the acid secretion, and later to neutralizing it by the alkaline product of the stimulated surface epithelium. I have found doses of two to four teaspoonfuls in a glass of water after meals very useful for temporary relief in hyperacidity of all sorts. Big doses such as Petri used (nearly two oz.) are likely to irritate the stomach and cause nausea. I have used it in conjunction with alkalies and oils and a proper diet.

Some new drugs have appeared for increasing the acid in the stomach. Acidol tablets which equal 12 drops of dilute HCl and are taken in a tumbler of water, have no advantage over the old acid preparation except convenience in carrying about, and cost much more. Oxyntin, which only increases the *combined* not the *free* HCl in the stomach can have little effect on peptic digestion.

Pankreon a preparation of pancreatin, much advertised and used on the continent, is claimed to be unaffected by the gastric fluids and to reach the bowel in an active state. The Council of Pharmacy of the A.M.A. found that it was promptly digested by pepsin in acid solution and thus rendered inert in the stomach before reaching the bowel.

Hormonal the peristaltic hormone of Zuelzer given with the object of physiologically stimulating peristalsis has proved so toxic and dangerous in occasional cases that it seems unwise to use it.

Anesthesin, an insoluble local anasthetic similar to Orthoform in its action, has proved useful in sensitive stomachs in nervous people. The modern method in all nervous dyspepsias, however, is to treat the patient more and the stomach less. We really depend on rest, hygiene, sedatives feeding up and encouragement, while most of the "special apparatus," intra-gastric douches, and electrodes, powder blowers, gyromeles, etc., which lumbered up the older textbooks on diseases of the stomach are rarely seen or used today.

Even lavage in spite of all the ingenious apparatus devised, is much less used than formerly, one reason being that the patient whose stomach persistently refuses to empty without help, wisely seeks a surgeon.

On the other hand not every patient with fasting residue in the stomach needs a surgeon. The stomach like the heart may have its periods of dilatation and decompensation and in some cases of atony and ptosis may fail miserably of emptying itself now and then. Here lavage with rest and diet may work wonders. I have seen within a week two patients of this type in whose fasting stomachs I found a half a pint of coarse food residue ten or fifteen years ago. Medical treatment gave prompt relief and they have been well for years.

Duodenal intubation is a new method used by Einhorn for treatment of peptic ulcer. A small soft rubber tube is passed into the duodenum and left in place continuously for ten or twelve days and food is poured through it directly into the bowel. The object is to free the ulcer from the irritation of food and gastric secretion and heal it quickly. A few men have used the method and reported good results, but it has not come into general use. I have tried it in a few cases with poor success. The constant presence of the tube was usually trying and the feeding often caused distress. I must confess that the continuous presence of an indigestible foreign body is not my idea of "giving the stomach a complete rest." The method is still on trial.

I have said nothing about diet in this brief review, not because it lacks importance, but because I have discovered nothing really new within the past year or two.

In surgery I notice less tendency to operate on non-obstructive peptic ulcers, evidently because the results have not been as good as in the obstructive cases. The x-ray clearly shows that in the former the food continues to pass out through the open pylorus instead of by the new surgical opening. The food continues to irritate the ulcer and the new opening tends to close and conditions are left as before operation. This makes the surgeon less eager to operate on some border line non-obstructive cases, and where operation is clearly indicated by reason of failure of medical treatment, inclines him to

close the pylorus at the time gastro-enterostomy is done.

SIGNIFICANCE OF MINIMAL MACROSCOPIC GASTRIC STASIS.

BY A. EVERETT AUSTIN, M.D., BOSTON,

Physician to Mount Sinai Hospital, Berkeley Infirmary and Assistant to Boston Dispensary.

VON NOORDEN long ago called attention to the fact that while the stomach was subject to abnormalities of secretion and motility, the latter, particularly when they produced retention, were the only ones to actually cause a change in the metabolism of the body, because much of the nutritive value of the food is destroyed by fermentative and putrefactive processes. True, the hypersecretions by producing pain induce the patient to eat less food, and emaciation follows, but if the patient can be assured that a generous, well selected diet is beneficial to his condition rather than otherwise, and is the very best means of controlling the suffering, an equilibrium can soon be established; this cannot be done where stasis exists dependent on pyloric narrowing, since almost every effort to increase the amount of nourishment is overcome by the periodical onset of vomiting or the increased distress of the victim. Hence it behooves us to detect the very earliest manifestations of retention in order to forestall the subsequent malnutrition. At just this point we come upon two causes of delay of gastric contents in the viscus, as unlike as the two regions are described to be where we are supposed to pass our future life. Unfortunately, too, the clinical signs in the early stages differ from each other only in degree and that largely of time. When retention or delay arises from gastric myasthenia, a meal of a beefsteak, four tablespoons of mashed potato and bread and butter should leave the stomach in eight hours while, if due to pyloric narrowing, it may not leave for fourteen hours. As can be seen, there is no hard and fixed line of division, yet everything depends on this decision for the following reasons: a gastric myasthenia is either associated with a general weakness of the whole muscular system so commonly seen in the Stiller type with narrow chest and acute substernal angle, concave epigastrium and protruding region about the navel, often congenital or is the result of a general enteroptosis following repeated child bearing, hernia, or the weakening of abdominal muscles by laparotomy scars. Here operation other than a shortening of the gastrohepatic ligament, whose value has not been fully demonstrated, is of no avail, and only roborant measures can be employed The other condition, true pyloric narrowing, is dependent on scar tissue from ulcer, cancer or adhesions from cholecystitis. Intermittent spasmodic narrowing due to gastric hypersecretion is maintained, but at least it cannot be common, and there must be periods when free egress of the contents occurs and retention of any considerable degree ceases. For stasis due to pyloric narrowing, only gastrojejunostomy gives any permanent relief, while this operation does not aid myasthenia in the slightest degree. Thus we are driven to employ our greatest ingenuity in separating these conditions so essentially unlike, but with such similar manifestations. Nor is it permissible to wait until visible peristalsis and gastric rigidity make the differentiation so evident that "He who runs may read." Then the stomach has become distinctly dilated and as a result of the fermentation and vomiting the patient has become more or less emaciated, adding greatly to the danger and prolongation of the convalescence from the operation which must follow. An illustration of this is shown in the following case.

CASE 1. A man, 42 years of age of excellent habits who had had "stomach trouble" not clearly defined for a long period (two or three years, as near as he could recall), began three months ago to suffer more severely. He had epigastric pain after every meal, but it was more severe when he ate heartily, for his appetite remained good. There were eructations of sour fluid 3-4 hours after the food and once in two days, particularly at night, vomiting of large quantities of sour tasting fluid containing recognizable food fragments without any particular association of pain other than the distress mentioned. He had lost 20 pounds in weight though he was eating well and his movements were irregular and induced largely by laxatives.

The physical examination showed excellent teeth, no cachexia, no glandular involvement, while the heart and lungs were without significance.

The stomach was found to fill the whole abdomen; spurting could be felt and heard over the pylorus, but there was no mass, no resistance, but little tenderness, and no gastric waves could be distinguished. The fasting stomach washings, 18 hours after food, contained all forms of food fragments with numerous sarcinae and free hydrochloric acid. The gastric contents six hours after a chicken sandwich amounted to 400 c.c., had a musty odor with many bubbles, and the solid portion was one-third of the whole. Free hydrochloric acid was present and the acidities were 33 and 98. Sarcinae were abundant, but there were no Boas-Oppler bacilli. The clinical diagnosis was pyloric stenosis due to ulcer. The surgeon's report was duodenal adhesions, scar of an old duodenal ulcer, constriction of the ascending portion of the intestine and collapse beyond. The stomach was enormously dilated but no glands were found anywhere.

Of course every effort should be made to make a much earlier diagnosis than was made in this

case, and various articles of food have been suggested which are known to leave the stomach with more or less difficulty, such as currants, raisins and rice, while it has come to my attention that lima beans, particularly the outer coverings, are long delayed in their departure. Then again we are advised to depend on the microscopical detection of food fragments at a sufficient period after an evening meal. Unfortunately, the former articles may pass out of a stomach with moderate pyloric stenosis within the prescribed time, as is shown by the following case:—

CASE 2. A girl of 29 years was well to 5 years ago, when she began to have pain coming on after eating. She remained in a hospital 8 weeks, where her stomach was washed out 30 times. She was better for 6 months, when her former pain after eating recurred. Two years ago she returned to the hospital, where her appendix was removed. Again there was a remission of her symptoms for 18 months, when her old symptoms returned much exaggerated. At present she has gaseous and fluid eructations which are very acid and come on one to two hours after food. She has pain at this time which she localizes over the old appendix scar.

If the pain is severe, she vomits, an event which occurs about 4 times weekly, and may occur at night; the vomitus is always very sour and contains food but never blood. She has lost 13 pounds in weight during the six months, but confesses that she has eaten much less for fear of aggravating the pain. Her bowels move every second day and the stools are very hard. Menses always painful and last 3 days but no clots are ever passed.

Physical examination showed a very pale individual with gums and conjunctivae almost colorless. The hemoglobin was 75% (Tallquist). The teeth were good, the tongue lightly coated, the chest narrow with acute substernal angle, but the heart and lungs were without significance. The stomach's dimensions were 21 vertical by 23 cm. horizontal, extending 5 cm. below the navel and 8 cm. to the right of the median line. There was a well defined tender spot just above and to the right of the navel and a spot of similar character in the right back just below the insertion of the tenth rib. What was taken for a contracted pylorus was felt under the tender spot in front, but no masses nor undue rigidity were detected. The fasting stomach after the evening Riegel meal with the addition of rice and raisins contained no gross food fragments nor mucus. The stool after three days' meat-free diet, contained no occult blood (modified Weber). After the test breakfast the gastric content had free hydrochloric acid with acidities of 60 and 85. There were no sarcinae nor mucus. The radiologist reported that the pylorus was well defined, the first part of the duodenum filled, an enlargement of the stomach in the longitudinal direction, and on standing the lower border was in the pelvis; no stasis could be discovered. The operation showed an ulcer scar on the posterior surface of the duodenum adjacent to the pylorus with numerous adhesions, for which a gastrojejunostomy was done.

It is almost incredible that there was not, at periods, sufficient pyloric narrowing to cause the vomiting, yet the raisins passed through without hindrance.

Then again we may err at the other extreme when some food residue is found by lavage of the fasting stomach, but the laparotomy shows no narrowing and the stasis must be ascribed to myasthenia, as is proven by the case which follows:

CASE 3. A man, 45 years of age, an architect, of excellent habits, using neither tobacco nor alcohol, had been well to two years ago, when a torticollis had been relieved by cutting the muscle, following which he had passed ten months in a sanatorium for neurasthenia. For the five months subsequent to his coming under my care he had had sour stomach, acid eructations, water brash, and his bowels had been confined, requiring the frequent use of laxatives. He thought he felt better when there was food in his stomach than when it was empty, but food did not play an important part in his discomfort. Eructations often continued for 6 hours after he had eaten. At no time was there any severe pain, except one night recently when the pain in the epigastrium was so severe that he vomited food which was extremely sour to the taste. He was sure the vomitus was not brown nor red. His weight had remained constant for many years at 153-5 and he weighed 155 in my office. Examination showed his head to be still slightly drawn to the left, his teeth good, his tongue but lightly coated and his sclerae free from yellowing. Sound heart and lungs were found and no involvement of the glandular system was discovered. His abdomen was full, symmetrical and without tender points. Under inflation the stomach extended from the 6th rib to two fingers above the navel on the left, while on the right it extended beyond its usual limit and the tympany encroached on the liver space. Under the right costal border a hard mass could be felt to slip under the examining fingers on full inspiration, but was not perceptible on expiration. It gave the impression of a sausage-shaped body, but only the lower border was perceptible. The fasting stomach after the evening Riegel meal contained food fragments in very diminutive quantities, upon lavage, among which the raisin fragments could be detected. After a test breakfast the contents contained no free hydrochloric acid, but the total acidity was 85. No sarcinae nor Boas-Oppler bacilli were found. The feces after a meat-free diet never contained occult blood. The urine was normal. The radiologist reported a stomach normal in size, shape and contour, but under the screen no food could be seen to pass through the pylorus. The individual was passed on to the surgeon with a provisional diagnosis of early malignant disease of the pylorus, when, much to my surprise, when the abdomen was opened by him an almost gangrenous gall bladder was displayed containing one large stone and much debris, but the pylorus was entirely normal and entirely free.

Under such conditions, of course, we must hold a myasthenia responsible for the minimal retention, but such an occurrence warns us against placing too much confidence in the slight stasis which this meager remnant or microscopic residue represents.

Much discussion has been aroused as to

whether, when lavage of the fasting stomach produces food fragments, while the radiograph at a six-hour interval shows no stasis, we are to place our reliance on the one or the other. It would seem that the explanation of the other horn of the dilemma, when radiology shows stasis and the tube does not, is not explainable by the bending of the tube by which it follows the lesser curvature, since it was one of the teachings of Boas that the lower border of the stomach could be determined by palpation of the tube after it was introduced. Especially when lavage follows, this explanation would be less tenable because, after the introduction of two liters of water, in four portions, any food residue must be brought to light unless we were dealing with an hour-glass constriction. Huerter thinks that the excessive hydrochloric acid in many instances of myasthenia keeps the pylorus closed much beyond its usual period, while the acid contents entering the duodenum are being neutralized and thus simulates a minor stasis when lavage is employed, while the neutralizing effect of the contrast meal (bismuth subcarbonate) checks this tendency when radiology is employed. If these premises are true, then in case of contradictory results, we must rely with greater assurance upon the radiologic method. At least we must employ both methods and, if they agree, we proceed to operative intervention with greater confidence. It has been my experience in many instances where lavage showed morning residue and the radiogram did not indicate stasis, that subsequent treatment with alkalies and atropine brought about a condition where lavage no longer brought forth food remnants under the same restrictions as formerly.

Now, since raisins have proved deceptive for testing motility and the so-called microscopic retention is evanescent, coming and going without any known cause, if many observations on a myasthenic individual are made, we must have recourse to some more reliable method for the detection of early pyloric stenosis. The criterion which I have adopted is the one recommended by Hausmann and consists of the retention of starch granules of sufficient amount to be visible to the eye at least 12 or more hours after a liberal portion of boiled rice or rice pudding has been eaten in conjunction with meat, potato, bread and butter. All patients after such a meal come to the clinic fasting, when they are washed out with one or two liters of water in portions of 500 cem., according to whether the first returns clear. As it is very difficult to determine whether a residue, if present, is made up of starch remnants or mucus mixed with partially digested epithelial cells, on account of the similarity of color, the washings are allowed to stand in a conical glass when the solid part will soon fall to the bottom. The supernatant fluid is then poured off and Lugol's solution added to the solid portion, with which it is thoroughly mixed. An instantaneous bluish coloration will appear, were the residue starch. No matter how small the remnant may be apart from mere isolated microscopic granules, it becomes readily visible and may be found as late as sixteen hours after the rice is taken where the stasis is marked, but still not so gross as to cause large accumulations of residual food in the stomach as is found in adadvanced pyloric cancer and callous ulcer. When this condition exists, which should be verified by at least two examinations, and better three at week intervals, I have always found that there is a pyloric narrowing due to organic disease, as verified by operation, or where that was refused, by steadily increasing difficulty in the stomach's emptying itself and greater residue in the period following. One must not rely upon a single instance of this occurrence, for I have repeatedly seen a fairly copious amylaceous residue at the first lavage, disappear at a subsequent washing, under the identical conditions as to amount of food and time, one week later.

Such temporary and periodic increase in the weakness of a myasthenic stomach to which such retention is due, arises from various causes. I have seen them after a severe cold where there has been much irritating cough, with an accession of constipation and more rarely when there is a coexisting chronic appendicitis. It has been my practice, too, to add the raisins to the evening meal, and have been very much surprised in routine washing of the fasting to note how infrequently fragments of the fruit can be found and how much more constantly the gross starch remnants are discernible when the residue is treated as suggested. There is no explanation for the fact that raisins will pass through an opening which will hold the rice back. Some have offered the explanation that it is not the narrowing as such that holds the rice, but the depression in the stomach's surface afforded by a chronic ulcer, much as the bismuth adheres which produces the flecks in the radiogram and persists on the wall of the organ long after the rest of the contrast meal has disappeared. If this is true, then the minimal macroscopic residue would have a double significance of pyloric narrowing or an old ulcer scar, not necessarily at the pylorus. My personal experience, however, has led me to believe on account of the ephemeral nature of this finding that it is due to myasthenia and for some unaccountable reason, the weakened stomach can free itself more readily from the raisins than from the starch. When the residue is persistent and there is progressive narrowing, then the rice and the raisins pursue a parallel course and both can be removed at every washing. Another suggestive factor in favor of the theory that microscopic amylaceous residue may be found from adherence to an ulcer scar is the simultaneous presence of bile in the wash water, while when any considerable amount of starch (*i.e.* macroscopic) is found, bile is rarely, if ever found. Hence microscopic starch granules with bile are indicative of chronic ulcer with imperfectly closing pylorus or an exaggerated myasthenia, while macroscopic rice rem-

nants without bile may be interpreted as meaning an actual stenosis without, of course, indicating its nature.

Naturally, too, when retention results from the idiopathic pyloric closure of hypersecretion or continuous secretion, if such exist, which many doubt, the bile is never found; such at least is my experience that when from the fasting stomach any considerable portion of highly acid clear gastric juice may be drawn, this is never stained with bile. Similarly, if the wash water responds promptly and markedly to reagents for free hydrochloric acid when it is impossible to express the undiluted contents, and any considerable amount of starch is found, our color reactions are rarely disturbed by the peculiar coloration of bile. We may summarize these isolated facts by saying that: (1) A limited number of rice grains visible in the wash water only by means of the microscope, 12 hours or later after the evening meal when accompanied by marked hydrochloric acid reaction or bile, means a spasmodic closure of the pylorus or a myasthenia and is rarely permanent. (2) Currants or raisins may be retained for this period in a myasthenic stomach or sometimes pass through a moderate narrowing of the pylorus. (3) A distinct amylaceous residue made visible to the unaided eye by means of Lugol's solution, which is not accompanied by bile, but is by hydrochloric or organic acids, if persistent, means a mechanical hindrance to the egress of food from the stomach. (4) A wash water containing hydrochloric acid freely and microscopic starch remnants may indicate an old ulcer scar without a trace of gastric stenosis. (5) A minor gastric retention detected by lavage and unconfirmed by the radiograph is proof of pyloric spasm rather than stenosis, and will often disappear upon appropriate medical treatment. (6) A radiographic demonstration of gastric stasis, not substantiated by lavage, is oftenest due to myasthenia since the weakened gastric walls cannot free the stomach from the heavy bismuth within the accepted time.

BANTI'S DISEASE WITH REPORT OF SUCCESSFUL SPLENECTOMY.*

BY MILTON G. STURGIS, M.D., SEATTLE, WASH.

IN 1866, Gretzel, describing enlargement of the spleen in an infantile case from the clinics of Griesenger, first used the term, "splenic anaemia." Previously, non-leukaemic enlarged spleens had been described as pseudo-leukaemias.

There were few cases reported from that time until 1882, when Banti, an Italian pathologist, published his studies of cases of splenomegaly of unknown etiology, concluding that they constituted a distinct clinical disease, and divided this disease into three stages.

First, the stage of splenic enlargement with secondary anaemia; second, the stage in which the liver becomes palpable; and third, the ascitic stage. The secondary anaemia presented a fairly distinctive picture, in which the numbers of erythrocytes were ordinarily decreased, but not constantly, the color index lowered, nucleated reds or myelocytes were never found, the hemoglobin was decreased, a leucopaenia was sometimes present.

He was the first to give a comprehensive description of the pathology of this disease, as follows:[1] The spleen is much increased, weighing from 1 to 1.5 kilograms. The shape is preserved, the surface smooth and regular. The capsule is thickened, and on section, the substance is dark brown and hard, showing thickened trabeculae and whitish nodules, which correspond to the Malphigian bodies.

Microscopically, the Malphigian bodies were found in various stages of fibrous transformation, the process beginning around the vessel, within the body. A certain amount of hyaline transformation was also apparent. The splenic pulp showed no special enlargement of the venous channels. In the earliest stage, there may be found in some of the veins, a lining of large cells, making the vessels appear almost like an epithelial channel on cross-section. These large cells have a limited amount of protoplasm, and large nucleus of a diameter of from 5 to 8 microns. The same kind of cells are found in the reticulum surrounding the veins, and in some of the channels, the cells have become loosened from the walls, and fill the lumen of the vessel, giving the appearance of a cancerous alveolus. In some spaces actual giant cells and occasionally cells containing normal or degenerated red corpuscles were observed. The reticulum of the pulp was evidently thickened and of a hyaline appearance. This was always a conspicuous feature, and distinguished the tissue absolutely from normal spleen. The thickening of the reticulum is in proportion to the duration of the disease, and, finally, areas of the splenic pulp may become entirely fibrous.

In view of the process of fibrous transformation, and the multiplication of cells within the veins, Banti proposed the name, "fibro-adenia." He does not believe there is a new-formation of fibrous tissue in the ordinary sense of the term, but rather, an increase of the reticulum, from exudation from pre-existing cells.

The liver is reduced in size, granular, and hard. In earlier stages of the disease, it may be normal in size, and smooth. Microscopically, there is found a marked inter-lobular cirrhosis like that due to alcohol.

Banti calls particular attention to sclerotic endophlebitis of the splenic vein, causing irregular thickening and sometimes even athermatous and calcareous foci. These conditions also extend into the portal vein, and in the

* Read before the North Pacific Surgical Society at Seattle.

ascitic stage of the disease, even the mesenteric veins may be affected, though in less degree than the splenic. He found the disease more common in males, in young adult life, and described a symptomatology dependent on the weight of the spleen, the anaemia and ascites. He believed the anaemia to be due to the increased hemolytic action of the spleen.

He based his opinion that the spleen is primarily responsible for the clinical picture, on the following considerations. First, splenomegaly always preceded the anaemia; secondly, hepatic changes appeared last of all; thirdly, the changes in the spleen seemed to him to be peculiar to the disease, and the success of splenectomy suggested the diseased spleen as the chief factor in the cause of the disease.

Since the publication of Banti's first article, much has been written on this topic, and a diversity of opinion expressed which is most confusing. At present there seems to be three divisions of thought. First, those agreeing with Banti that the disease as described by him, constitutes a distinct clinical entity, accounting for a part of the splenic anaemias. Second, those who believe that Banti's Disease is but the terminal stage of primary splenic anaemia. Third, those who believe that it is not a primary disease, but is secondary to cirrhosis of the liver—a pre-cirrhotic splenic tumor.

In the cases recorded in literature so great has been the variation in the pathology, in the blood picture, and in the duration and intensity of the symptoms, that most clinicians and pathologists agree that Banti's Disease as a clinical entity does not exist; but reserve the term for the terminal stage of primary splenic anaemia, which, they agree, is a fairly definite clinical entity of unknown origin, characterized by a chronic course;—enlargement of the spleen, anaemia of a secondary type, a marked tendency to hemorrhage, and a liability in late stages to be associated with jaundice, cirrhosis of the liver, and ascites.[2]

As to the cause of this primary splenic enlargement, it has been suggested that it results from toxines absorbed from the gastro-intestinal tract, but this has not been proven; that it is secondary to the endo-phlebitis of the portal and splenic veins, but experimental studies occluding partially or wholly the splenic veins have failed to produce anything but primary congestion, followed by partial or total atrophy; that it is due to stasis in the portal circulation, but the splenomegaly always occurs before stasis is established; that there is a relationship between splenomegaly and tuberculosis, syphilis, or chronic malaria, regarding which it is interesting to note that Cohen of Philadelphia reports a case of typical clinical splenic anaemia where, after the use of large doses of quinine, plasmodia were found circulating in the blood. Recently, Gibson[3] reported that in five cases of Banti's Disease, a post-mortem study of the spleens disclosed a streptothrix present in each one.

Banti's theory of the anaemia being due to the increased hemolytic action of the spleen is acceptable to Rodman and Willard,[4] who draw an apt comparison between the hyperactivated thyroid exerting a deleterious action on the body, which is ameliorated or cured by the partial or total removal of the thyroid, and the hyperactivated spleen producing symptoms which are likewise relieved by the removal of the spleen. Others, notably Dock and Warthen and Stengel[5] take the stand that this is due to a bradyplastic condition of blood-forming organs and point to the fact that they found a marked hyperplasia of the hemo-lymph glands lying along the thoracic aorta and in the retro-peritoneum, which contained large numbers of cells holding red blood corpuscles and blood pigment, and in view of the pathology of the spleen, they concluded that this condition was compensatory.

Whether or not splenic anaemia can be considered as a clinical entity is still unsettled. We have a disease, the pathology of which is due to a chronic toxic irritant, having a selective action on the spleen; whether this toxin arises from one or several causes, is unknown but the work but recently done by Billings[6] in the treatment of Hodgkin's Disease, as well as the discovery that eclampsia is but the expression in the kidneys or liver of a ferment generated in the pathologic placenta, leads us to believe that this discovery when made, may change our entire conception of this disease.

The history of the case reported is by Dr. Moser who referred the patient.

A. W. White boy, aged 18. Family history negative. Father, mother, brothers and sisters, all living and well.

Patient came to us June 1, complaining of being continually tired, and of having a sense of fullness and dragging in left hypochondriac region. For the previous two years the patient has a sense of not being well, with intermissions of relative improvement; he noted times when his skin had a distinct yellowish color; various physicians had told him that he had liver trouble, for which he was treated. He was irritable and refractory to parental control; appetite was poor, often being entirely absent, and was somewhat perverted; at times he was nauseated and would vomit. This latter was apparently uninfluenced by the kind of food taken, or by the time of ingestion.

Of previous illness, the patient had had measles; no malaria, and no evidence of ever having lived in a malarial country. In July, 1909, he had received a gunshot wound, which necessitated amputation in the upper third of forearm. There ensued a discharge of pus from the wound and from an axillary abscess, which was cured by "scraping the bone" under anesthesia.

The patient is slender, of poor musculature, drooping shoulders, slow gait, and tired facies; the conjunctivae are jaundiced, as is the skin of the entire body. The teeth are sound. The gums are firm, and have no dark colored line on them. The

tonsils are neither enlarged nor scarred. The pupils are equal and react to light and distance. The thyroid gland is not enlarged; the thymus is not detected; the lymphatic glands are not generally palpable. The heart action is good; the apex beat inside the nipple line in 5th intercostal space. There are no murmurs, nor arrythmia. The lungs have good excursion, and no abnormal respiratory sounds are detected.

The abdomen has full contour, and is slightly distended. No "Caput Medusae" is present, and the navel is retracted. There is dullness in the flanks, which dullness seems to shift with changes of body position. The liver is not palpable at border of right costal arch.

The spleen can be easily palpated, and its lower border extends one-fourth of the way from left costal border to the umbilicus; it is not rigidly fixed, but is slightly movable; percussion over the splenic tumor elicits flatness.

Neither kidney is palpable. No varicosities exist in the lower extremities.

The patient was under our care from this time until a splenectomy was done upon him in December.

Our treatment consisted of a thirty days' course of iron plus Fowler's solution, as tonics and alteratives: salol and occasional exhibitions of calomel.

In August the patient became worse, having a remittent fever, of two weeks duration, ranging from 100° to 101° F. He had, at this time, a number of hemorrhages into the stomach with hematemesis, the blood being dark red in color, and slightly digested. Blood was also present in his urine. The hemoglobin fell to about 65%.

The hemorrhages were treated by complete rest in bed, fluid diet, ice to the abdomen, and calcium lactate, grs. x. t.i.d.

Following this time in August, the patient improved somewhat in weight and strength, his hemoglobins came up to about 80% and he had no visible hemorrhages. No examination was made for occult intestinal blood.

Urine: S. G. 1015, color—pale straw, no sugar, no albumen, indican occasionally, blood was present after during the month of August, about 1500 c.c. daily.

Blood: Hemoglobin 65-80%, leucocytes 8000, erythrocytes 4,000,000.

Differential count: Polys. 65, large monos. 5, small monos. 25, eosinophiles 3, transitional 2.

The reds were regular in size, and were evenly stained. No nucleated reds were detected.

At the time of the operation the liver dullness extended a finger's breadth below the ribs. The edge of the spleen was palpable two-thirds of the distance to the umbilicus.

Operation. Dec. 4, 1912. Incision 8 inches long was made through left rectus muscle. There was free fluid in the abdomen. Owing to severe perisplenitis, there was a band of extremely vascular adhesions an inch or more in width, extending from the one side of the splenic vessels around the border to the other side. The omentum was adherent to the anterior surface. Because of the density of the adhesions it was impossible to first clamp off the splenic vessels as is ordinarily done. The adhesions were stripped off, the bleeding being controlled by gauze, until the spleen was entirely free; it being then removed without difficulty. On removal of gauze there was slight bleeding, which was controlled by ligature, excepting a small area on the posterior surface of the diaphragm, where extensive oozing necessitated packing.

The wound was closed, and the patient returned to his room in considerable shock. He was suitably stimulated, and rallied well. There had been no traction on, nor injury to, the stomach, but seven hours after operation he vomited brown fluid, an hour later he vomited about three ounces of dark red blood, and shortly after, a large amount of blood clots. Twelve hours after operation, his temperature was 102° F., pulse 128, and respiration 34. He vomited dark blood each day for four days, and passed a large dark fluid bowel movement on the fourth day.

On the fourth day he developed a cough—a mild bronchitis—which persisted during his stay in the hospital, causing him very much discomfort.

The packing was removed on the third day, and the patient was able to leave the hospital on the 25th day. His temperature persisted at 100° to 101° F., up to the time of his leaving the hospital. Excepting this, he was in good physical condition, and had recovered a fair degree of strength.

Pathological report by Dr. O. J. West:—

Macroscopical Examination. Spleen 22 x 17 cm., weight 800 gms., normal shape preserved, color normal, surface smooth. Capsule is markedly thickened and shows evidence of extensive adhesion on anterior surface; cut surface, dark red except where ramifications from capsule penetrate to form trabeculae; these trabeculae are much thickened.

Microscopical Examination. Malpighian bodies show moderate fibrous increase; endothelial lining of vessels is hypertrophic and occasionally vagrant endothelial cells are seen. No malignancy, no infection necrosis or degeneration.

The findings are those of a chronic toxic spleen, with nothing to designate the source or nature of the toxic substance.

He suffers no discomforts and apparently enjoys excellent health; yet an examination of the blood made Feb. 28, 1914, shows the following condition. Moderate poikilocytosis and anisocytosis.

Number of leucocytes per cm. (estimated) 8000

Differential count of leucocytes:—

Lymphocytes	43%
Large mononuclear and transitional	15%
Neutrophiles	34%
Eosinophiles	8%

This case presents some interesting features. The abnormalities of the blood 14 months after the removal of the spleen suggests that the anaemia is not due to hemolytic action of the spleen alone. In view of the findings of Gibson the history of the trauma to, and amputation of, the arm with resulting infection, followed within a year by the primary symptoms of this disease which were progressive up to the time of the removal of the spleen suggests that such infections may be the origin of the toxin.

AN OPERATION FOR CORRECTING THE AQUILINE NASAL DEFORMITY. THE USE OF A NEW INSTRUMENT. REPORT OF A CASE.*

By Oliver A. Lothrop, M.D., Boston,

Assistant Otologist, Massachusetts General Hospital; Clinical Assistant, Massachusetts Charitable Eye and Ear Infirmary.

The nasal deformity often called the aquiline or Roman nose, is characterized by an excessive growth forward from the face of the nasal bones and septal cartilage, causing a hump or arching forward of the nose bridge. In extreme cases a very disfiguring deformity results, most noticeable in profile. In order to transform such a deformity into a normal nasal profile, this new operation has been devised.

General anesthesia is required for this operation and adrenalin chloride, applied to the mucous membrane of the septum and nasal bones, is very helpful in reducing the hemorrhage. Strict asepsis in every particular throughout the operation is imperative for a good result.

Technic. An incision is made on one side of the columella down on to the free edge of the septal cartilage. The muco-perichondrium is now elevated for a short distance on either side. If the septal cartilage has grown too long in this direction, so that the nose is too long and hangs over the upper lip, a suitable amount of the denuded cartilage is now removed. The muco-perichondrium is then elevated on both sides of the septum close under the nose bridge up to and under the nasal bones. The free border of the cartilage forming the bridge is now shaved down to the line desired for the reconstructed bridge. A piece of the perpendicular plate of the ethmoid close under the nasal bones is now removed, relieving all support at that point.

The next step in the operation consists in making an incision within the nostril along the free border of the nasal bone and ascending process of the superior maxilla. This incision cuts the mucous membrane and underlying tissues adherent to the free border of the bones and brings the operator beneath the periosteum covering the external surface of the nasal bone and ascending process. The periosteum elevator now raises all the periosteum over the nasal bone and ascending process of that side. The above technic is now repeated on the other side.

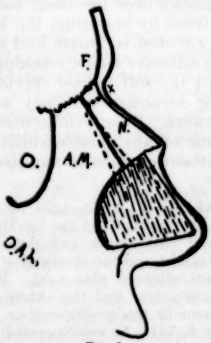

Fig. 2.

This figure shows the septal cartilage (shaded) with its re-shaped borders and the skin and soft tissues collapsing upon them. *N.* Nasal bone. *A.M.* Ascending process of superior maxilla. The broken lines enclose the triangular section on either side of the nose which must be removed to meet the newly-shaped border of the septal cartilage before depressing the arch formed by the nasal bones. *X.* At this point the nasal bones are fractured with a narrow chisel. *F.* Frontal bone. *O.* Orbit.

A triangular or v-shaped piece of bone is next removed subperiosteally from either side of the nose. This section includes a little of the nasal bone and some of the ascending process and has its acute angle near the fronto-nasal suture. In oder to remove this section cleanly, symmetrically and quickly, a new bone punch was devised for this operation. It is a heavy forceps just small enough to enter the vestibule, having a male blade and a female blade. The female blade has a triangular aperture, one-quarter of an inch at the base and seven-eighths of an inch on each of the other sides. The male blade fits into this area so that with one closure of the forceps the desired section can be removed.

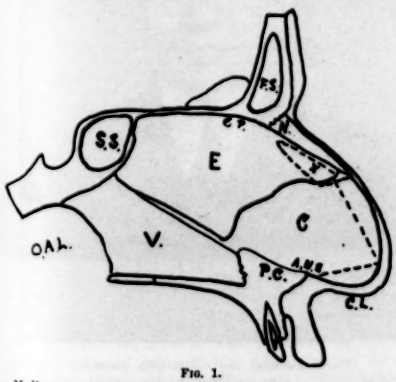

Fig. 1.

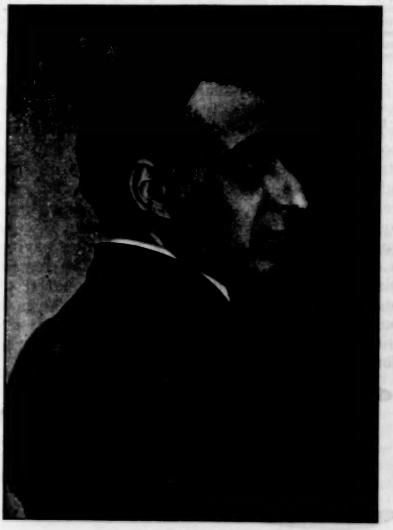
Fig. 3.

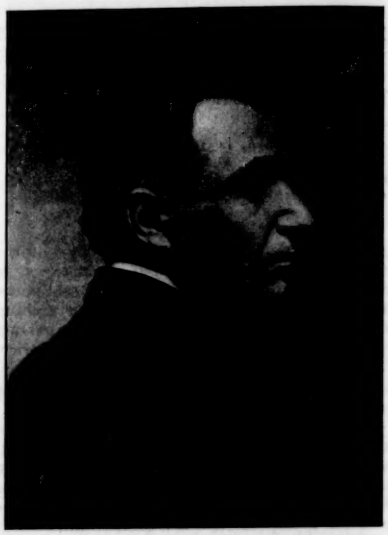
A new bone punch designed to remove a V-shaped section of bone.

* Read at a meeting of the New England Laryngological Society, March 24, 1914.



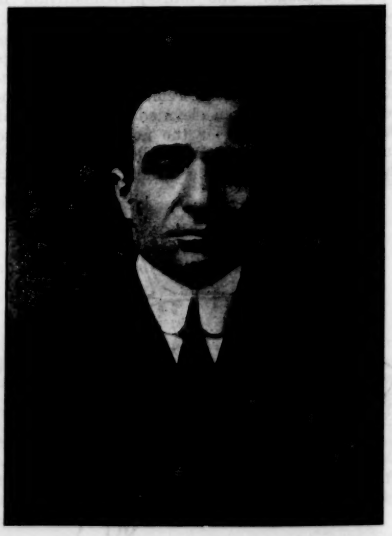
After the lateral V-shaped sections have been removed the nasal bones are fractured near the fronto-nasal suture with a narrow straight chisel. Protecting the soft tisues over the nasal bones, the latter can now be easily depressed with a blow from the mallet flush with the newly-shaped, free border of the septal cartilage.

If the nose is of the proper length the operation is finished. No packing or splinting is required. Light gauze pressure may be used over the nose for a few hours if desired to prevent a hematoma.



Should the nose be abnormally long, cartilage is removed from the free border at the columella as previously mentioned. Since all attachments of the soft tissues over the nasal skeleton have been cut or freed by elevating, the nose can be shortened to any desired length and held in that position with adhesive strips reaching on to the forehead until the soft tissues (periosteum) readhere to the reconstructed bony and cartilaginous framework. This technic makes possible the shortening of any nose exclusive of other deformity without excision of any tissue causing external scar.

CASE REPORT. G. J., male, aged 30 years, medical student, was referred to me by Dr. Augustus Riley for nasal obstruction and deformity. The septum was straight and the obstruction complained of was due to collapsed alae nasi. Examination was otherwise negative and the external nasal deformity is shown in the accompanying illustration.



On January 9, 1914, he was operated upon. The technic of operation was identical with that above described. The operation consumed forty minutes and the patient made a good ether recovery. He never had any pain but there was considerable swelling and ecchymosis. His temperature recorded on a four-hourly chart, never went above the 98.6 line. On the fourth day after operation he left the hospital, at which time the swelling was

Photograph taken before operation showing the aquiline deformity and drooping tip of the nose.

Photograph taken two months after operation showing the results of correction.

Front view taken two months after operation.

rapidly subsiding, but it was not wholly gone for over two weeks. The adhesive plaster was removed on the third day and there was no tendency to elongation of the nose. However, to insure against a return to the former condition, the plaster strips were left in place for over two weeks. At present the nose is three-eighths of an inch shorter than before operation, the bridge is straight, and the nose is perfectly firm. The nose is still a little broader than before operation, which is probably due to periosteal thickening. Although branches of the nasal nerve must have been cut, patient observed no change in sensation at the tip.

One most gratifying, although perhaps unexpected, result of the operation was the marked improvement in breathing, noticed by the patient the first day after operation, notwithstanding the swollen condition of the nose. The shortening had relieved the collapsed condition of the alae nasi and had opened up the vestibules so that the patient had good breathing space.

ANAPHYLACTIC REACTIONS OCCURRING IN HORSE ASTHMA AFTER THE ADMINISTRATION OF DIPHTHERIA ANTITOXIN.*

BY J. L. GOODALE, M.D., BOSTON.

THE following paper is intended as a preliminary communication regarding the local phenomena occasioned by horse serum in individuals suffering from so-called horse asthma.

It has long been known that animals may be sensitized by an injection of foreign serum and examination of the literature shows a number of instances in man where a second injection of horse serum has been followed by alarming and even fatal results. It has also been observed that individuals who are subject to horse asthma may show anaphylactic shock, when given antitoxin from horses even though they have not previously been given an injection of horse serum. The suggestion was made by Rosenau and Anderson that these individuals may have been previously sensitized by the inhalation of particles of flying hairs from horses, carrying minute quantities of protein, causing local sensitization.

From these reports, it is sufficiently evident that the injection of horse serum in sensitized individuals may be extremely hazardous. We have, however, no observations, showing whether asthmatics in general are more subject to this danger than other individuals. Furthermore no studies have been made, so far as I know, to ascertain whether individuals suffering from horse asthma are actually peculiarly susceptible to horse serum.

* Read before the Boston Society for Medical Improvement, March 23, 1914.

In order to determine whether horse serum was capable of producing local disturbances at the point of contact, patients with a history of vasomotor disturbances were examined in one or both of the following ways.

1. The lobe of one ear was moistened with a drop of diphtheria antitoxin prepared by the Massachusetts State Board of Health, and a superficial cut was made with a needle, just sufficient to cause blood to appear, but not to flow.

2. A drop of the same antitoxin was placed in one nostril upon the anterior end of the lower turbinate.

Eighteen cases were examined. These may be grouped as follows:

1. Cases in which horses had been known to excite nasal vasomotor symptoms or an asthmatic attack.

2. Cases showing no reaction to horses, but in whom the asthma was apparently associated with bronchitis alone, or occurred only during the summer in connection with hayfever.

Eight cases with a history of sensitiveness to horses were examined with the following results:

CASE 1. Miss W., 28. For eight years asthma more or less constant throughout year, increased markedly by the neighborhood of horses. Has been under observation for six years. A large cystic right middle turbinate was removed in 1909, without influence on asthma. Tonsils were removed for septic detritus four years ago. During past two years, asthma had been much less troublesome, and is able to drive behind horses, although the air of a stable excites an attack.

A drop of diphtheria antitoxin was placed in each nostril. Within five minutes the mucous membrane of both lower turbinates and of the septum became pale, edematous and covered with serous fluid. The clinical picture was that of typical hay fever, and the symptoms passed off in the course of two hours. A week later a scratch was made in the skin of the lobe of one ear, and the same antitoxin applied. In three minutes the patient stated that the ear itched, and examination showed a white, slightly raised area of the skin immediately surrounding the scratch, while the skin beyond this white area showed reddening and general swelling, the lobe of the ear as a whole being about twice the thickness of the other. Five minutes later the white wheal had disappeared, and the surface of the skin was diffusely reddened. In the course of the next hour the edema of the lobe began to diminish and two hours later had disappeared.

CASE 2. Mrs. V. Seen first in 1906 for asthma of many years' duration. Had had much treatment of nose without effect. In intervals of the attacks, chest examination was negative. Has had one or two small dogs continually about her. For several years following the first examination, it was observed that on being away from the dogs, she was free from asthma, and an attempt was made to have her dispose of the animals, but without success. In November, five years ago, she was given pollantin by her family physician for an attack of sneezing and moderate asthma. This was immediately followed by exceedingly severe dyspnea, nasal ob-

struction, and profuse watery flow from the nose, being the worst attack that she had ever experienced. The symptoms subsided in the course of twelve hours. Two years ago both dogs were disposed of on account of old age, and the patient has since then had no dogs in the house. During this period she has been entirely free from asthma, although a sense of constriction in the chest is experienced when in the neighborhood of horses. When I explained the test which I wished to make, the patient was unwilling to have the antitoxin applied to the nose, as her recollection of the asthma following pollantin was so disagreeable, but consented to have the test made on the ear. Within two minutes after the application of antitoxin to the scratch on the lobe of the ear, a clearly defined, elevated, white area appeared, bordering the scratch, surrounded by a diffuse reddening, the whole lobe becoming symmetrically swollen, this resembling perfectly the appearance on the skin which would be produced by a nettle. Five minutes later the white area became changed to red as in Case 1, and the local manifestations cleared up slowly in two hours.

CASE 3. Miss J., 24. Seen in 1909 for recurrent colds and asthmatic attacks since three years of age, always excited by horses, although also occurring at all times in the year, often without assignable cause. Bilateral ethmoiditis existed, characterized by enlargement of the middle turbinates, and polypoid degeneration of the mucous membrane. In 1910 the ethmoid cells were curetted, and the patient experienced complete relief for a period of ten months, when slight shortness of breath developed. One year later, in November, asthma appeared following a cold, and a return of polpoid tissue was observed in the right ethmoid region. This was curetted with relief from the asthma. In March of this year, the patient was tested by the methods above described, with positive result, one drop of the antitoxin in the right nostril causing a typical vasomotor swelling and pallor of the mucous membrane, completely obstructing respiration on that side, and attended by profuse watery discharge, the other side remaining unaffected. The right eye became suffused with free lachrymation. The skin test of the ear developed in four minutes as a clearly defined anemic area of one-fourth inch in width bordering the incision, and contrasting sharply with the hyperemic neighborhood. The whiteness of this area was especially well-defined against the generally reddened lobe, fading in four minutes, leaving a generally reddened edematous lobe, which returned to normal in three hours.

CASE 4. G. T., male, 24. Seen in February of this year for acute ethmoiditis, which cleared up after ten days. There was an old right chronic ethmoiditis with polyp formation. Polypi had been removed in the past on several occasions. The patient stated that during the summer the neighborhood of horses would occasion sneezing, and what he described as asthmatic feelings. This condition was apparently not sufficient to cause much discomfort. The serum test in the nose gave a delayed reaction, occurring in about half an hour, and lasting for two hours later. The serum test on the skin gave negative results.

CASE 5. Miss G., 24. Seen last summer for nasal obstruction and vasomotor rhinitis, aggravated in the neighborhood of horses. During the following winter she was seen on three occasions for nasopharyngeal catarrh, and stated that she was at this season able to go near horses without symptoms. A serum test of the nose gave no reaction.

CASE 6. Miss C. Seen May, 1913, for perennial vasomotor rhinitis, increased by the neighborhood of horses in summer. No asthma. During the winter is able to come near horses without symptoms. The serum test in the nose gave negative results. The skin test was not applied.

CASE 7. J., male, 23, brother of Case 3. In general well. Sneezed since boyhood whenever is in the neighborhood of horses. No asthmatic symptoms. Submucous resection has been done by another physician one year ago. Except for small septal perforation, nose essentially negative. Introduction of antitoxin into nostril not followed by reaction Skin test on ear negative.

CASE 8. E., male, 60. Hay fever many years. Horses excite sneezing and watery nasal discharge, but no asthmatic symptoms. Chronic non-suppurative ethmoiditis and polypi. The serum test of the nose was negative. On the skin a delayed reaction occurred, beginning in forty minutes, and lasting two hours.

Five cases of bronchial asthma which gave no history of irritation from horses were examined by the nasal test with negative results. Five cases of uncomplicated hay fever received the serum in the nose without exciting reaction.

SUMMARY OF CASES.

In three cases of horse asthma the application of horse serum to the nasal mucous membrane, (in one case pollantin) or to a cut of the skin gave rise to an immediate reproduction in miniature of the phenomena of anaphylactic shock, namely spasm of the arterioles, with oedema and surrounding congestion.

One case of horse fever gave a delayed but otherwise typical skin reaction, but no disturbance in the nose. One case of horse fever gave a delayed reaction to the nasal test, but was negative for the skin test. Four of the horse fever cases without asthma were negative for both tests. Five cases of bronchial asthma and five cases of hay fever without sensitiveness to horses gave negative results.

The number of cases thus far tested is too small to justify definite conclusions in regard to the value of these tests in detecting the existence of a state of sensitization to horse serum, but if further studies should confirm them, they should prove to be of assistance to the physician who is in doubt whether in a given case it is safe to administer antitoxin.

So far as they go, they would indicate that in horse asthma, an anaphylactic reaction may occur after the administration of horse serum; in horse fever with nasal symptoms alone, this danger is less or not at all to be feared, and in other types of asthma and of vasomotor rhinitis it is not present.

Clinical Department.

BILATERAL SARCOMA OF UNDESCENDED TESTES.*

By Oliver C. Smith, M.D., Hartford, Conn.,

Surgeon to the Hartford Hospital.

When some weeks ago the author looked through the literature on malignant diseases occurring in the undescended testicle he was surprised at the paucity of the same. Shortly after a splendid article with a thorough review of the literature on the subject appeared in the December number, Vol. 17, of *Surgery, Gynecology and Obstetrics*, by Dr. Kenneth Bulkley of New York City. Fifty-seven cases of malignant degeneration of the undescended abdominal testicle were found on record, to which he added two, making 59 cases, after an exhaustive search of foreign and domestic literature. Sarcoma of one type or another occurred in 40 of these 59 cases. Of this number the side was reported in 56 instances; 30 were upon the right, 24 were upon the left, and two were bilateral.

Since this article appeared the author has made a further search of the literature, believing that other *bilateral* cases must have been reported, as in Dr. Bulkley's collection cases of intra-abdominal testes only are cited. In a careful search, however, including a perusal of the catalogue of the Surgeon-General's library, no other cases of bilateral malignancy of testicles were found. The rarity of the condition would seem to make it proper to report the following case of bilateral sarcoma of undescended testicles.

H. M., aged 38, native of United States, farmer, white, married, no children; referred by Dr. R. E. Harrington, Stonington, Conn.

Family History. Father died of heart disease; mother living, has general dropsy; one sister living and well. No tuberculosis or malignant disease in family.

Personal History. Patient has never been seriously ill and enjoyed good health until onset of present trouble. As a child both testes were absent from the scrotum; occasionally the left one could be felt in the canal. At thirty years of age he suffered from parotitis, complicated by painful swellings in the inguinal canals. These swellings entirely subsided, and not until two months prior to our observation of him, did he notice an enlargement in each inguinal canal, the right being the larger. Their growth was rapid, the one upon the right side occasioning some pain.

Condition at Time of Examination. July 8, 1913. A tall, sinewy, bronzed, thin man of quiet demeanor, rather slow of comprehension, with masculine traits not well marked. Heart sounds were normal; lungs clear and resonant; reflexes active; no palpably enlarged glands. Blood-pressure, 120 mm. hg; hemoglobin, 80%. The prostate and seminal vesicles were normal to palpation, and the urine was negative. Both iliac fossae and inguinal canals were occupied by large, fluctuant tumors, the right extending from the upper margin of the scrotum to above the umbilical line. This mass was tense, fluctuating, and bulging far anteriorly to the abdominal wall. The tumor upon the left side occupied the inguinal canal and was less tense, and through the fluid medium could be palpated a solid, ovoid mass at the upper posterior area. Both testes were absent from the scrotum.

Diagnosis. Bilateral hydrocele with neoplastic degeneration of both testes high in the inguinal canals.

Fig. 1.
Photograph of patient taken previous to operation.

Figure 1 is a photograph of patient taken previous to operation. Operation July 10, 1913, at Hartford Hospital, under ether anesthesia, drop method.

An oblique incision was made on the right side, parallel to Poupart's ligament over the center of the tumor; the external oblique fascia was split as in operation for hernia. An enormous fusiform cyst of the tunica-vaginalis was found containing 750 c.c. of clear straw-colored fluid. At the upper portion a hard, irregular mass, the neoplastic testicle was found. The tissues of the cord, including the vessels and lymphatics, were dissected beyond the internal ring; the vas deferens was followed as far down as possible toward the pelvis and removed. A similar operation was performed upon the left side, where the quantity of fluid was found to be half that of the right. The testicular tumor was found lower in the canal than upon the right side, of similar appearance and but slightly varying dimensions. The wounds were closed without drainage. The operation was followed by but little reaction, and primary union resulted.

Figures 2 and 3 are photographs of the testicles after removal, actual size.

* Read before the Surgical Section of the Hartford Medical Society, December 22, 1913.

FIG. 2.
Photograph of left testicle after removal, actual size.

FIG. 3.
Photograph of right testicle after removal, actual size.

Figure 4 is a photograph of the patient taken seven months later, showing extensive recurrence on the right side.

The pathological report by Dr. John Carter Rowley, pathologist at the Hartford Hospital, was "large, round-celled sarcoma of each organ."

Figures 5 and 6 are photomicrographs by Dr. Arthur J. Wolff and show very clearly the histological structure.

The following is Dr. Wolff's description of the sections: "The sections were stained with a modified Van Gieson stain. The histological structure of both pieces of tissue are entirely similar, so that a description of the one applies to both. They consist of large, round cells imbedded in a scanty amount of intercellular substance; the stroma intervenes between all the cells and is closely connected with them. The sections show a rich but a very irregular distribution of small blood vessels possessing but a single layer of endothelial cells separating these from the round cells forming the tumor.

FIG. 4.
Photograph of patient taken seven months after operation, showing extensive recurrence on right side.

As can be seen in the photomicrograph of the right testicular growth, the large, round cells are in very marked mitotic action. In some parts of the tumor, especially near the peripheral zone, some disposition to alveolar structure is to be seen, but such arrangement is entirely absent in the deeper portions of the mass. The histological diagnosis is "large round cell sarcoma."

From the statistics collected by Dr. Bulkley it appears that malignant disease of the testicle is fifteen times as frequent in the undescended as in the scrotal testicle. It is obviously important, therefore, to place the undescended testicle in the scrotum during childhood, either by manipulation and massage, or by operation. Where this cannot be accomplished, removal of the undescended testis should be considered.

The newly built Institute of the History of Medicine will be opened in the University of Vienna at the beginning of the summer semester. Already the institute has a library of three thousand volumes, besides a number of valuable manuscripts relating to the Vienna Medical School. There is also a collection of old surgical instruments and apparatus.—*British Medical Journal.*

NEW ENGLAND PEDIATRIC SOCIETY.

The thirty-first meeting of the New England Pediatric Society was held on March 20, 1914, at 8.15 p. m., at the Boston Medical Library.

FRITZ B. TALBOT, M.D., Secretary.

DISCUSSION.

DR. WALTER B. SWIFT: I saw these cases in the Boston City Hospital, nerve out-patient department, and it may be of interest to know that they were put on thyroid extract there without any results whatever. This was done with Dr. Fairbanks' prophecy that no change would come. In looking over the German literature I find there are some cases, two in brothers, that have been reported: Porter, 1907, three brothers, and Schemensky, 1912, two brothers, twins.

counts for the characteristic deformity seen in this condition, of which these two children are most typical examples.

The particular interest of these cases shown this evening lies in the fact that we have here two very characteristic cases of the condition in two children of a family all of the other members of which are normal.

It has been reported that a chondrodystrophic mother has given birth to a chondrodystrophic child. On the other hand, a chondrodystrophic mother has given birth to normal children.

It would seem more probable that we have to do in these cases with an intrinsic germinal defect rather than with an acquired embryonic condition or disease. Certainly the condition has nothing to do with rhachitis, for the pathological process is entirely different in the latter disease, and the term "fetal rickets" should not longer be employed as synonymous for its condition.

am asking these questions for information, not criticism. I have seen a number of these cases, and all have been in girls. In one case I feared we might have some tubercular trouble and had Dr. Ernst go over the case carefully. He found the colon bacillus and there was no tubercular infection whatever. I have seen cases extend over two years' time where the colon bacillus was present.

DR. WYMAN, in closing: As to the transparietal theory, I cannot answer that question. I think that in a number of cases the condition clears up entirely. In some of the more acute cases the condition clears up in a month or six weeks. The chronic cases do not clear up as easily, and one often finds them extending over a year or sometimes years in spite of careful treatment.

With the alkaline treatment I give enough to get a strong alkaline reaction in the urine. (If I do not get it with grains ten, three times daily, of the ci-

NEW ENGLAND PEDIATRIC SOCIETY.

The thirty-first meeting of the New England Pediatric Society was held on March 20, 1914, at 8.15 p. m., at the Boston Medical Library.

Fritz B. Talbot, M.D., Secretary.

Dr. A. W. Fairbanks showed two cases of

CHONDRODYSTROPHIC DWARFS (BROTHERS).

Dr. Fairbanks, in commenting on the two chondrodystrophic dwarfs shown, said that such cases were entirely unrelated to hypothyroidism. He had seen a number of cases in children and three in adults and they were all free from myxoedematous phenomena and were normal mentally. One of the cases seen originally in childhood has been under observation nearly twenty years. These two brothers are mentally normal for their age and are doing the usual school work for that age. All of the other children and both parents are of normal stature. The mother and sister were shown for comparison.

The mother's pregnancy with both of these boys was normal in every respect.

Photographs of other cases in children were shown, as well as radiographs of cranium, extremities and thorax of each of the brothers.

The condition is due to defective growth of cartilage, the normal development of which should take place, or at least commence, between the third and the sixth month of fetal life, and to premature ossification of this deficiently developed cartilage, with consequent defect in the subsequent development of the bones. Only those bones are involved that develop from cartilage, and only those the cartilage of which should be in active growth in those particular months of fetal life, namely, the endochondrium of the long bones of the extremities, and the cartilage from which are formed the bones of the cranial base, the ribs and the pelvis. The limitation of the disturbance to this particular period of fetal life, and to the structures of the prospective bony framework whose development should normally commence in this period, but does not, accounts for the characteristic deformity seen in this condition, of which these two children are most typical examples.

The particular interest of these cases shown this evening lies in the fact that we have here two very characteristic cases of the condition in two children of a family all of the other members of which are normal.

It has been reported that a chondrodystrophic mother has given birth to a chondrodystrophic child. On the other hand, a chondrodystrophic mother has given birth to normal children.

It would seem more probable that we have to do in these cases with an intrinsic germinal defect rather than with an acquired embryonic condition or disease. Certainly the condition has nothing to do with rhachitis, for the pathological process is entirely different in the latter disease, and the term "fetal rickets" should not longer be employed as synonymous for its condition.

DISCUSSION.

Dr. Walter B. Swift: I saw these cases in the Boston City Hospital, nerve out-patient department, and it may be of interest to know that they were put on thyroid extract there without any results whatever. This was done with Dr. Fairbanks' prophecy that no change would come. In looking over the German literature I find there are some cases, two in brothers, that have been reported: Porter, 1907, three brothers, and Schemensky, 1912, two brothers, twins.

Dr. Edwin T. Wyman read a paper on,

PYELITIS IN INFANCY AND CHILDHOOD.*

Abstract: A review of the symptomatology, diagnosis, prognosis and the treatment of pyelitis.

He states that these cases of pyelitis are not infrequently treated for other diseases and reports two typical cases where the diagnosis was overlooked.

He states that in a series of cases of pyelitis in infants and children at the Children's Hospital, Boston, 54% were in infants under two years of age and 40% over two years. Of these cases 63% of the infants were females and 90% of the children were females. Vomiting was noted in 35% of the cases, painful micturition in 36%, and frequency of micturition in 40%. Chills were noted in 15%, and abdominal pain in 16% of the cases.

The average leucocyte count in the uncomplicated cases was 19,000; the lowest leucocyte count was 8,000, in a chronic case, and the highest leucocyte count was 62,000, in a very acute case. The temperature varied from normal in the chronic cases to 105.5° F. in the acute cases. There was anorexia, anemia, fretfulness and loss of weight in all cases.

DISCUSSION.

Dr. Myron L. King: I would like to ask Dr. Wyman what proportion of the cases clear up entirely? Do they entirely clear up, or do they run for years and years?

Dr. Edwin P. Stickney: One thing that surprised me was the size of the dose of these different drugs, and *especially* the citrate of potash. Do such large doses upset the stomach? In these cases I never use such large doses, and I wonder if the other gentlemen are accustomed to give them? I am asking these questions for information, not criticism. I have seen a number of these cases, and all have been in girls. In one case I feared we might have some tubercular trouble and had Dr. Ernst go over the case carefully. He found the colon bacillus and there was no tubercular infection whatever. I have seen cases extend over two years' time where the colon bacillus was present.

Dr. Wyman, in closing: As to the transparietal theory, I cannot answer that question. I think that in a number of cases the condition clears up entirely. In some of the more acute cases the condition clears up in a month or six weeks. The chronic cases do not clear up as easily, and one often finds them extending over a year or sometimes years in spite of careful treatment.

With the alkaline treatment I give enough to get a strong alkaline reaction in the urine. (If I do not get it with grains ten, three times daily, of the ci-

trate of potassium, the dose is increased to twenty grains three times daily. With the hexamethylenamin, I push the dose until I get the test for formaldehyde in the urine, keeping the urine acid all the time, and then if there is any microscopic blood in the urine, you know that there is irritation of the kidney, when the treatment is discontinued. With regard to citrate of potassium disturbing the digestion, in my experience I have not found it to do so.

DR. Z. B. ADAMS read a paper on,

THE ANOMALIES OF THE LUMBO-SACRAL REGIONS AND THEIR RELATIONS TO THE CAUSE OF SCOLIOSIS.*

ABSTRACT: First is mentioned the fact that congenital lesions of the base of the spine are frequent occurrences in scoliotics, more frequent than has been previously supposed; then follows a description of the mechanics of the base of the normal spine; the joint between the fifth lumbar vertebra and the top of the sacrum and between the sacral segments; the various anomalies at this region are rehearsed, special attention being drawn to those which have a bearing on the causes of scoliosis; next is a chapter on the mechanics of the scoliotic spine, but especially of the base, in scoliosis; next diagnosis is treated and the frequency of these lesions is brought out in an analysis of twenty-six cases, a brief description of the X-rays taken in making the diagnosis. In speaking of treatment the importance of these anomalies is shown, and it is brought out that it is a mistake to attempt to make the corrected spine stand upon the twisted and uneven base, from which it has toppled; therefore it is necessary to place and fix the base of the spine in a position of equilibrium, so that the corrected spine may stand upon it. This requires careful surgical treatment after corrective methods have been practised.

DISCUSSION.

DR. TALBOT: We have had the privilege tonight of hearing some entirely new principles in the mechanics of scoliosis, and I am told that these principles which Dr. Adams has worked out are going to revolutionize the treatment of that condition.

DR. RICHARD M. SMITH read a paper on,

FAMILY INCIDENCE OF ENDOCARDITIS IN CHILDREN.

ABSTRACT: Out of 208 cases of endocarditis, chorea or rheumatic fever 30, or 14.48%, occurred in children who had father or mother or brother or sister with a similar infection.

Some families had all the children showing infection. In some cases the date of the onset of symptoms of the different members of the same family suggested strongly infection from one individual to another.

DISCUSSION.

DR. HENRY I. BOWDITCH: I would like to ask Dr. Smith whether there was any similarity between the infections, what proportion of the cases in a given family had chorea, and what proportion had rheumatism, and whether they all followed a certain course. I think this study is extremely interesting, and opens our eyes still further to the possibilities of infections. We may have to come to the point of isolating such families because of the transmission of dangerous organisms.

DR. L. C. MILLER: Dr. Smith stated in his remarks that the social worker looked up these cases. I would like to ask him if she reported on the surroundings, hygienic conditions, etc., and how much bearing they may have had on the course of these conditions in different members of the same family.

DR. ARTHUR W. FAIRBANKS: In those cases of endocarditis that result from tonsillitis it seems to me that there can be no question of familial incidence in the strict sense of the term, that is, a familial predisposition to the disease. There can be no question about the infectious and contagious nature of acute tonsillitis. We have all of us seen many examples of this in families and in institutions. Now if such infections result in endocarditis, that endocarditis cannot be considered as indicative of familial incidence, but is better termed a familial accident. It is the result of infection transmitted from one individual to another by contact, as in the case of any other infection.

We of course see cases of rheumatism with endocarditis, and chorea with cardiac involvement occurring in more than one member of a family without any obvious infectious disease like tonsillitis having preceded their onset. Whether the entrance of the infection in cases is by some other route than by the tonsils we cannot say, but the resultant endocarditis is the accidental result of infection rather than the result of familial predisposition.

DR. SMITH, in closing: I would say in reply to Dr. Bowditch's question as to whether one family was more prone to have rheumatism, another chorea, and so on, that we did not find that this was so. There may be three children in the same family, and one of them may have chorea and rheumatism, while the other two have other conditions,—they do not necessarily have the same condition.

Answering Dr. Miller as to the question of surroundings, we tried when we started out to go into the question of surroundings, physical conditions, etc., but we were unable to get sufficient data from which to draw accurate conclusions. Cases of endocarditis following tonsillitis do not fall into the group under discussion, and there are a great many such cases.

Another illustration of this possible infection of rheumatic fever from one member of the family to another may be worth mentioning. A case came to my attention today where two boys had been in the habit of sleeping in the same bed. One fell sick and the brother was taken away to sleep in another room. The first boy proved to have rheumatic fever and for four or five days he slept alone. When the joints quieted down, the other boy resumed sleeping with him, and the next day he came down with rheumate fever. This may be a pure coincidence, but it seemed to me a rather striking occurrence.

PLAGUE IN COLOMBIA.—Report from Bogota on May 7 states that bubonic plague has broken out along the Atlantic coast of Colombia. Suppressive measures have been immediately instituted. The number of cases is not given.

* See BOSTON MED. AND SURG. JOUR., Vol. clxx, No. 21, May 21, 1914, p. 786.

Book Reviews.

Diagnosis in the Office and at the Bedside. The Use of Symptoms and Physical Signs in the Diagnosis of Diseases. By Hobart Amory Hare, M.D. New (7th) edition, thoroughly revised and rewritten. Octavo, 547 pages. Philadelphia and New York: Lea and Febiger. 1914.

Dr. Hare has revised his book, which is now in its seventh edition. He has omitted laboratory methods from the text. A very careful index is an excellent feature.

Diseases and Deformities of the Foot. By John Joseph Nutt, B.L., M.D., surgeon-in-chief to the New York State Hospital for the Care of Crippled and Deformed Children. New York: E. B. Treat and Company, 241-3 West 23rd Street. 1913.

This monograph, designed to cover all the common disorders of the feet, in large measure accomplishes its purpose. If there is a slight lack of an original point of view, the thoroughness with which the foot conditions of all sorts are described makes it a very useful book. It is evidently written rather more for general practitioners than for orthopedic surgeons, and wisely it does not attempt to describe the details of complicated operative procedures. The illustrations, especially the line drawings, are profuse and graphic, those which portray the commoner types of deformity of poliomyelitis being most excellent. The book will help to call attention to a region which suffers much from medical ignorance and inefficiency.

Die Krankheiten der Nase und Mundhöhle, sowie des Rachens und des Kehlkopfes. Ein Lehrbuch für Arzte und Studierende. Von Dr. Alfred Bruck, Berlin. Zweite, wesentlich vermehrte und verbesserte Auflage. Mit 252, zum Teil farbigen Abbildungen und 2 Tafeln. Urban and Schwarzenberg. 1912. New York: Rebman and Company.

This is the second edition of an excellent textbook. With German thoroughness and system it divides and subdivides, but it is condensed and clear. It has a little to say about everything and not too much about anything. To the American reader the method of dealing with the tonsils will appear ancient, but on the other hand, he will find some subjects which he has probably never heard of before. The first edition of this book was translated into English four years ago by Dr. Ross of Edinburgh and published in this country. It is reviewed in this Journal, Vol. 163, p. 262.

Chronic Colitis. Its Causation, Diagnosis and Treatment. By George Herschell, M.D., and Adolphe Abrahams, M.D. London: Longmans, Green and Company. 1914.

The authors state that they have designed this book for the general practitioner. In their definition of chronic colitis they exclude the condition of ulceration of the intestine except in so far as it is definitely considered a complication of chronic colitis. They regard ulcerative colitis as a specific infective condition which is the province of the surgeon. Most readers will wish a work that is less elementary and more critical. On the whole, the work is rather vague and general.

A Text-Book of Physiology. For Medical Students and Physicians. By William H. Howell, Ph.D., M.D., professor of physiology, Johns Hopkins University, Baltimore. Fifth edition, thoroughly revised. Octavo of 1020 pages, fully illustrated. Philadelphia and London: W. B. Saunders Company. 1913.

In the new edition of this well-known textbook the author has maintained admirably the high standard set by previous editions. While the frequent issuance of new editions of necessary text-books is to be deplored in general, it seems to be unavoidable in any field in which advance is so rapid as in the medical sciences. An unfortunate feature of the situation is that in the most rapidly developing phases of a subject, material advance may be made during the interval between preparation of the manuscript and issuance of the text-book. This is exemplified in interesting fashion in the discussion in Professor Howell's book of internal secretions. His treatment of the functions of epinephrin represents the utmost that could be said in the summer of 1913. But in the months that have elapsed since then, some very striking advances have been made in our understanding of the operation of this hormone. Thus nothing is said in the text-book about the "emergency function" of epinephrin, although in the light of the most recent researches that expression seems to elucidate its actual use in the body better than the more detailed statements previously given.

Probably the most significant advance in the present edition over previous ones, lies in the sections devoted to the absorption of the various food stuffs, and to general metabolism. The recent work of Mendel and Osborne, Folin and Denis, and the other workers in these fields, is

presented with full appreciation of the great gain in our comprehension of these difficult topics which their work has furnished. Scattered throughout the book are to be found such changes in statement as the general physiological advance of the last two years has made necessary. While one might possibly wish that the recent studies having to do with the mechanism of muscular contraction had received more attention, in view of the great complexity of this subject and the lack of finality about the experiments, the postponement of the discussion to later editions is undoubtedly justified. That the book as a whole constitutes one of the most satisfactory presentations of the subject matter of physiology in any language, cannot be doubted.

The Early Diagnosis of Tubercle. By CLYDE RIVIÈRE. New York: Oxford University Press. 1914.

Any new book by such an authority as Dr. Rivière merits close attention and scrutiny. The present volume is a small one of nearly pocket size with, however, 260 pages.

The reviewer frankly does not like the title. While the author evidently means the early diagnosis of pulmonary tuberculosis, certainly the title does not convey this idea. As is common with many books of this type, it loses much of its value as a help to general practitioners in this important branch of medicine on account of the multiplicity of detail. The description of fine technical points in diagnosis would tend to diminish the relative importance of the fundamental groundwork on which the early diagnosis of pulmonary tuberculosis rests. For the specialist in tuberculosis and diseases of the lungs there are many points of interest, although many with which American students of tuberculosis would not for a minute agree. The reviewer is strongly of the opinion that there is not anywhere near enough attention given to the history, occupation and constitutional signs and symptoms of the patient and far too much space devoted to the detailed examination of the lungs. The author is an enthusiastic advocate of percussion as a means of diagnosis, and in the reviewer's opinion somewhat exaggerates its value and does not pay enough attention to auscultation.

Under the subject of differential diagnosis, he speaks of apical pulmonary collapse and acute apical catarrh, chronic bronchitis with collapse, as simulating early pulmonary tuberculosis. The cases which he presents as examples of this condition unfortunately do not give enough data to allow of an opinion one way or the other. It would be far safer to consider the cases which he presents as ones of early pulmonary tuberculosis rather than of pulmonary collapse or apical catarrh.

There is a detailed discussion of tuberculin in diagnosis, far too detailed for the general practitioner to understand or to be even interested in. The best feature of the book is a detailed discussion of tuberculosis of thoracic glands, or hilus tuberculosis. This is most interesting and valuable and presents this subject in fuller detail than the reviewer has seen elsewhere in any other book or publication. There are many photographs, diagrams and charts.

With the exceptions mentioned above, there is very much to commend itself in this little volume, although it is one evidently intended more for specialists than for the average general practitioner.

Scrofulosis. By PROFESSOR DR. G. CORNET, Berlin. Translated from the second German edition by J. E. BULLOCK, M.D., London. New York: William Wood and Company. 1914.

After a careful study of this book, the reviewer is as much at a loss after having read it as he was before so doing as to what scrofulosis is, and as to its relation to pulmonary tuberculosis. In general, there seem to be two causes of this strange condition: (1) scrofulosis due to the tubercle bacillus; and (2) scrofulosis due to various pyogenic organisms. In reading over the various conditions due to scrofulosis, one finds that the seborrhea of the scalp in young infants, and large tonsils and adenoids in childhood, eczema in all of its forms in all ages, glands of the neck, all forms of tuberculosis, and all diseases due to pus-forming organisms, are due to scrofulosis or to the scrofulous diathesis. The reviewer regrets that he cannot see how this book can cause anything but confusion worse confounded, and utterly fails to see its place in the medical literature of this country at least. The therapeutic advice here given would seem to hark back to a period of twenty-five years ago. Creosote, in various ingenious mixtures, arsenic, cinnamic acid, sapoviridis, and others are recommended. The author even devotes half a page to the rubbing in of brown soft soap from the neck to the popliteal space as a cure for tuberculosis, glandular swellings, ulcers, etc.

Although in certain passages there is much sound advice in this book, as a whole the reviewer believes that such a volume as this will do far more harm than good.

The Junior Nurse. By CHARLOTTE A. BROWN, R.N. Illustrated. Philadelphia and New York: Lea and Febiger. 1914.

This volume is primarily a text-book for probationers. It describes the things a nurse should know and learn to do early in her training. It is a well-written book, illustrated with 41 good figures in the text, and should find a place of definite value in the library of training-schools and of the individual pupil nurse.

THE BOSTON

Medical and Surgical Journal

THURSDAY, MAY 28, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

TRANSMUTATION AND RACE-BUILDING AMONG BACTERIA.

IT has been recognized in the past that there may be considerable variation and transformation in the biological characteristics of different bacterial species. Progress in this direction has been carried forward to such an extent that we are now confronted with evidence that transmutation of one species of bacteria to another has been accomplished, thus questioning the permanence of bacterial species.

These transformations or transmutations of bacteria have been brought about by modification of the environmental conditions through experimentation. We find that Thiele and Embleton[1] report the experimental transformation of Bacillus mycoides into an organism resembling the bacillus anthracis. The former bacterium is a non-pathogenic organism found in garden soil, slender, non-capsulated, flagellated, motile, growing at a low temperature, and dying when incubated at body temperature. The latter organism is pathogenic, shorter and thicker, encapsulated, non-flagellated, non-motile, capable of growing at body temperature, virulent, having all the properties of the bacillus anthracis and producing lesions quite similar to those found in anthrax. In like manner these authors have converted the harmless smegma bacillus into a virulent bacillus which resembled the tubercle bacillus in all its properties, and the various relatively avirulent diphtheroid bacilli have been transformed to virulent organisms which in every way resembled the diphtheria bacillus.

Rosenow,[2] of Chicago, has recently made noteworthy and valuable contributions to this fascinating and important problem of the transmutation of bacterial species. In his recent paper in the *Journal of Infectious Diseases*, he first refers to the work of investigators in the problem of the transformations among the various strains or types of streptococci, and then gives the results of his own extensive experimentation and observation. Five different micro-organisms were employed in these experiments. They were the streptococcus viridans, the streptococcus hemolyticus, the streptococcus mucosus, the streptococcus rheumaticus and the pneumococcus.

The extent of his observations can be judged from the fact that they comprised the following: Culturing of the micro-organism under varying favorable and unfavorable conditions, with a study of the morphologic biochemical and virulent properties of the various strains of cocci employed. The organisms were cultivated in various and widely different environmental conditions, such as, for instance, cultivation in an atmosphere varying from pure oxygen to complete absence of oxygen, in media with a salt concentration varying from hypertonic to hypotonic, at temperatures slightly above and slightly below normal body temperature. Various body fluids, such as ascitic fluid, urine, sterile milk and others, were employed. Furthermore, the various micro-organisms enumerated above were grown in symbiosis with other organisms, within the cavities and circulating blood of living animals. Still further, the organisms used in this extensive series of experiments were obtained or isolated from a great many widely different sources, including tonsillitis, arthritis, erysipelas, puerperal sepsis, pneumonia and others. The bacteria so obtained were subjected to the various experimental environmental conditions mentioned above.

As a consequence of this work Rosenow found the following results: Apparently complete transmutation of each of the various members

[1] *Ztschr. f. Immunitätsforsch. u. exper. Therap.*, 1913, xix, 643.

[2] Transmutations within the Streptococcus-Pneumococcus Group, *Journal of Infectious Diseases*, 1914, xiv, 1. Also Relation of and the Lesions Produced by the Various Forms of Streptococci with Special Reference to Arthritis, *Illinois Medical Journal*, xxv, 1, 11; Rôle of the Streptococcus in Rheumatism, Muscular and Articular, *Journal of Infectious Diseases*, January, 1914.

of the streptococcus-pneumococcus group to one or the other of the rest of the group was accomplished *in vitro*. So complete was the transformation in some of the strains that it was found to be so by every test known. Thus the transmutation into another type of organism and the identity of the latter was proved by the morphologic and biochemical characteristics, the fermentative powers, presence or absence of capsule, solubility or insolubility in bile and sodium chloride solutions, the behavior toward the respective broth culture filtrates (Marmorek's test), and the specific immunity response as proved by the production of specific opsonins and agglutinins, and the more or less specific pathogenic powers as evidenced in the ability to produce characteristic lesions when inoculated into animals. For example, strains corresponding to hemolytic streptococci were converted into typical pneumococci as determined by all the tests enumerated and vice versa. In other words, the streptococcus was transformed from one strain to another and to a pneumococcus and vice versa, as proved by morphologic, cultural, agglutinating, pathogenic and other properties.

It has thus apparently been demonstrated that one species or race of bacteria can be transformed or transmuted into another. A new species of bacteria, a new race of micro-organisms has been developed by the modification of certain environmental conditions. Rosenow further noted that the various strains with which he experimented seemed to have a more or less specific affinity for certain specific structures in the body, one attacking the joints with the production of arthritis, another the lining of the heart with resulting endocarditis, another the muscles, producing myositis.

As Rosenow points out, this work was started by others before him and no doubt anticipated by still others before them, since it was fully appreciated that differentiation and specialization of function was here at its minimum, in as much as in dealing with bacteria we have to do with the very lowest forms of life.

The importance of these findings for bacteriology, epidemiology, medicine and biology, are not yet fully appreciated by many. But Rosenow ventures to say that the fact that variations in oxygen tensions and salt concentrations, that growth in symbiosis with other bacteria and that injections into body-cavities in animals, commonly produced mutational forms in streptococci, suggests strongly that similar changes might occur in various foci of infection where such conditions may prevail. "It would seem, therefore," he declares, "that focal infections are no longer to be looked upon as merely a place of entrance of bacteria but as a place where conditions are favorable for them to acquire the properties which give them a wide range of affinities for various structures."

MEDICAL LEGISLATION. REORGANIZATION OF THE STATE BOARD OF HEALTH.

THE bill for reorganization of the Massachusetts state board of health, the text of which was printed in full in last week's issue of the JOURNAL, has been first referred by the legislature to the committee on ways and means. On Tuesday, May 19, this committee held a hearing at which Governor Walsh spoke in favor of the bill. Others who spoke in its favor were Dr. Bowers, in behalf of the legislative committee of the Massachusetts Medical Society, Mr. Stoughton Bell, for the Boston Chamber of Commerce, and Drs. Edward O. Otis, James J. Minot, and Arthur K. Stone. Many amendments were offered. It is estimated that the expenses of administering the new system would be about $16,000 more than the cost of the present board.

Opponents of the bill criticise it because it does not transfer the department of vital statistics from the secretary of state to the health service, and because it makes no provision for adequate control of the milk supply. It is a debatable question whether such provisions should be made a part of the present bill; whether they could not more properly be made the subject of special legislation. It is also suggested that the health commissioner should be given even larger jurisdiction and authority. This, too, is a legitimate question for discussion in committee and before the legislature. As it stands, we believe the bill a constructive and dignified piece of legislation, and, with such modifications as may seem desirable, advocate its enactment into law.

It is to be realized that Dr. Walcott's retirement marks the end of an epoch in health administration; and that methods which were efficient with the board of his time, may no longer be adequate under the changing conditions and personnel of the future.

HEALTH EDUCATION.

It is evident that increasing publicity in regard to matters of health is to be the prevailing attitude of the future. If this is accepted it is eminently desirable that such instruction as is given in physical and mental hygiene should be from authoritative sources. Among such efforts toward public enlightenment we are glad to call attention to a series of small pamphlets which sell at the modest price of four to ten cents bearing the general title, Health Education Series. These small booklets, as they are termed in the prospectus already number 29, on such subjects as "Milk," "Colds," "Meat and Drink," "The Boy and the Cigarette," "Microbes, Good and Bad," "Emergencies,' "Industrial Hygiene" and others of like character. These are written by such authorities in their several subjects as the late Dr. Charles Harrington, Miss Ellen H. Richards, Professor C.-E. A. Winslow, Dr. Edward O. Otis and other persons of equal attainment in their special fields. Undoubtedly such pamphlets, obtainable at so small a price, will be helpful to a large number of people. Evidently the writers have been chosen with care to the end that the suggestions made shall lead directly to a more adequate knowledge of the laws of health through a plain statement of the means for their attainment. We wish to call special attention to the latest of the series by Dr. Charles M. Green on the subject "Prospective Motherhood," a subject upon which it will be generally acknowledged a large amount of ignorance exists. Dr. Green has approached his topic on the basis of a wide experience in a way which cannot fail to be of value to women looking forward to motherhood. If the precepts therein expressed were generally followed there is no doubt that much discomfort and actual illness both before and after childbirth might be avoided.

HOSPITAL PROVISION FOR WHOOPING-COUGH.

There is at present pending before the Massachusetts General Court a bill for the abolition of the parental school at West Roxbury. The school department, it is understood, already has in hand plans of making other provision for the children annually committed there. If this bill is passed, it is proposed to convert the buildings of the parental school into a hospital for whooping-cough. At present there is no hospital provision for cases of pertussis, which are never admitted to the South Department of the Boston City Hospital. During the decade from 1901 to 1911 the annual average of deaths from this disease was 76 per 10,000 inhabitants. In 1910 the rate was only 52 but in 1913 it rose to 97.

Whooping-cough, though unfortunately often lightly regarded by the public, is an important disease of childhood, serious in its course, complications, and sequelae. It has a considerable mortality, often due to neglect of proper treatment. The possibility and risks of its general dissemination from unisolated cases are great. Dr. John Lovett Morse has recently emphasized the importance of making hospital provision for this disease, and steps to this end have already been taken in New York. It is to be hoped that the above measure, or one similar to it, may soon adequately be carried out in Boston.

DEFEAT OF THE ANTI-VACCINATION BILL.

The anti-vaccination bill met with an overwhelming defeat in the House on May 14. The vote stood at 133 to 53. Largely owing to the influence of the Christian Scientists the contest was fierce and persistent. The Senate had already approved of the measure, 25 to 9, and the sponsors had great expectations of victory.

Great credit is due Dr. E. H. Bigelow who led the fight in the House. He made the principal speech, exhibited pictures and charts to show the effects of smallpox in contrast to vaccination and did much to convince the open-minded members of the advantages to be derived from the operation. The replies of the State Board of Health to the series of questions suggested by Representative Chamberlain of Springfield also had their effect. Mr. Moore of Leominster and many other public-spirited members of the House deserve the gratitude of the friends of good government for their wise action in defeating the bill.

A MEDICAL VIEW OF THE DWARFS AND JESTERS DEPICTED BY VELASQUEZ.

IN an interesting article of recent date in *Aesculape* Verdier has brought to the attention of the medical world the great attraction which the depiction of the deformed and mentally deficient toys of royalty had for the great Spanish painter. After paying homage to the greatness of Velasquez, Verdier brings out the deep knowledge of pathology possessed by the painter in his startling, life-like depiction of these unfortunates. No modern physician could have told Velasquez the points to bring out in accentuation of the abnormalities of face and figure better than he knew them himself. No artist, said Verdier, had a like power to understand the temperament or the mentality of these people. The dwarfs depicted he finds indisputable examples of pathologic states. The pictures of Philip IV, especially, Verdier says, are the most penetrating psycho-physiologic analysis that an artist has ever made.

MEDICAL NOTES.

CANADIAN ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.—The fourteenth annual meeting of the Canadian Association for the Prevention of Tuberculosis will take place at Halifax, N. S., on July 13 and 14, 1914. Dr. S. Adolphus Knopf of New York has been invited to deliver the oration on that occasion. The subject will be "The Modern Warfare Against Tuberculosis as a Diseases of the Masses," His Royal Highness, the Governor-General of Canada, is the Honorary President of the Association.

OFFICERS: AMERICAN DERMATOLOGICAL ASSOCIATION.—At the thirty-eighth annual meeting of the American Dermatological Association, held in Chicago, May 14-16, 1914, the following officers were elected for the ensuing year: President, Dr. S. Pollitzer of New York; vice-president, Dr. Martin F. Engman of St. Louis; secretary and treasurer, Dr. Oliver S. Ormsby of Chicago. It was decided to hold the next meeting in New York City in May, 1915.

APPOINTMENT OF DR. SMITH AT THE ROCKEFELLER INSTITUTE.—It is announced that Dr. Theobald Smith, professor of comparative pathology in the Harvard Medical School, has accepted the position of director of the new department of animal pathology at the Rockefeller Institute for Medical Research.

AN HEREDITARY CENTENARIAN.—Bridget D. Curran, who died on May 15 at Bethlehem, Pa., is said to have been born in 1807. Her mother is reputed to have lived to the age of 102, and her grandfather to that of 108.

BUBONIC PLAGUE IN HONGKONG.—Report from Hongkong states that 203 cases of bubonic plague occurred in that city during the week ended May 6.

HOSPITAL BEQUESTS.—The will of the late Catharine Paris, of Boston, contains bequests of $10,000 each to the Sacred Heart Hospital, Manchester, N. H., and St. Mary's Hospital, Quincy, Ill.; $5000 to the Home for Convalescent Women, Spring Valley, Ill.; and $3000 to the Claremont (N. H.) Hospital.

NATIONAL ACADEMY OF SCIENCES.—At a meeting of the National Academy of Sciences on April 23, in Washington, D. C., Dr. Walter B. Cannon, Higginson professor of physiology at the Harvard Medical School, was elected a member.

BUBONIC PLAGUE IN HAVANA.—Report from Havana on May 15 states that another case of bubonic plague has been discovered in that city, making a total of 17 since the outbreak of the present infection.

BENETOL IN THE TREATMENT OF HOG CHOLERA.—Report from Minnesota to the United States Department of Agriculture on May 15 states that in experiments by Prof. H. C. Carrel and Dr. E. W. Berg, benetol has been found of great value in the treatment of hog cholera.

HONOR FOR DR. REMSEN.—At a recent meeting of the Chicago section of the American Chemical Society, Dr. Ira Remsen, emeritus president of Johns Hopkins University, was decorated with the Willard Gibbs medal for his distinguished researches in chemistry.

AMERICAN ASSOCIATION OF PATHOLOGISTS.—At the Toronto meeting of the American Associa-

tion of Pathologists, April 10 and 11, papers were read by representatives from the Harvard Medical School as follows: Dr. M. M. Canavan and Dr. E. E. Southard, "Further Studies in the Bacteriology of the Cadaver"; Dr. H. T. Karsner and Mr. Cyrus H. Fiske, "The Effect of Acute Destructive Lesions of the Liver on its Efficiency in the Reduction of the Ammonia Content of the Blood"; Dr. S. B. Wolbach "Concerning the Granule Stage and Filterability of Spirochaetes"; Dr. S. B. Wolbach and Dr. Richard S. Austin, "The Cultivation of a New Filterable Spiral Organism from Human Feces"; Dr. Richard P. Strong and Dr. E. E. Tyzzer, "The Pathology of Oroya Fever and of Verruga-Peruviana"; Dr. E. E. Southard and Dr. M. M. Canavan, "On the Incidence and Nature of Renal Lesions in Subjects Dying Insane"; Dr. H. T. Karsner and Dr. F. G. Benedict, "Pathological Lesions following Prolonged Exposure to Atmospheres Rich in Oxygen"; Dr. H. T. Karsner, Mr. H. H. Amiral, and Mr. A. V. Boek, "A Study of the Influence of Splenectomy and of Certain Organs and Organ Extracts on the Hemopsonins of the Blood Serum"; Dr. J. Earle Ash, "Primary Carcinoma of the Liver" and "Primary Carcinoma of the Lung"; Dr. A. E. Taft and Dr. M. E. Morse, "On a Cerebellar Lesion and Associated Lesions of Dentate and Olivary Nuclei."

St. Mary's Hospital, Rochester.—The recently published twenty-fourth annual report of St. Mary's Hospital, Rochester, Minn., records the work of that institution for the calendar year 1913. During this period, the total number of patients treated was 7020, upon whom 10,166 operations were performed, with a total death rate of 1.5 per cent. Ten patients were not submitted to operation. From the training school 19 nurses were graduated.

Escape of Early the Leper.—Report from Seattle, Wash., on May 19 announces the escape of John R. Early, the leper from the Diamond Head quarantine station near Port Townsend. He is believed to be in hiding at Victoria, B. C.

BOSTON AND NEW ENGLAND.

Smallpox in Attleboro and Boston.—On May 19 a case of smallpox was discovered at Attleboro, Mass., and another in Boston. Neither of the patients had ever been vaccinated.

Scarlet Fever in Milton.—Report from Milton, Mass., on May 16 states that five cases of scarlet fever have recently occurred among pupils of the Milton Academy, which has been quarantined to prevent further spread of the infection.

Children's Hospital Training-School.—The annual graduating exercises of the Children's Hospital School of Nursing were held at the Harvard Medical School on Friday afternoon of last week, May 22. The principal address was made by Dr. Harold C. Ernst. Dr. Frederick C. Shattuck presided.

Faulkner Hospital Training-School.—The annual graduation exercises of the Faulkner Hospital training-school for nurses were held at Jamaica Plain on Tuesday afternoon of this week, May 26.

Deaconess Hospital Training-School.—The sixteenth annual commencement exercises of the training-school for nurses of the New England Deaconess Association were held in Brookline on Wednesday of this week, May 27. The principal address was made by Dr. Daniel Fiske Jones, of Boston, and diplomas were presented to the six members of the graduating class.

Hospital Gifts and Bequests.—A friend of the Sharon Sanatorium has recently presented it $5000, to establish there an x-ray plant for scientific investigation.

The will of the late Francis Skinner of Dedham, Mass., which was filed in probate at that town on May 17, contains a bequest of $10,000 to the Massachusetts General Hospital.

Prevention of Infant Mortality.—On Monday afternoon of last week, May 18, a joint meeting was held in Boston of the Women's Municipal League and the American Association for the Study and Prevention of Infant Mortality. Dr. J. Whitridge Williams, president of the Association, professor of obstetrics at the Johns Hopkins Medical School, made the principal address on the subject of infant mortality, before and after birth.

Fire at Boston State Hospital.—On the morning of Thursday, May 21, a fire occurred in the two-story brick laundry building adjoining the Boston State Hospital, Dorchester. None

of the patients was disturbed and the damage was limited to $1000.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending May 19, 1914: Diphtheria 42, of which 4 were non-resident; scarlatina 91, of which 8 were non-resident; typhoid fever 5; measles 125; smallpox 1; tuberculosis 65, of which 2 were non-resident.

The death-rate of the reported deaths for the week was 14.86.

NEW YORK.

MORTALITY STATISTICS.—The death-rate in the city during the month of April was considerably lower than in the preceding month. The weekly reports of the Health Department show that the mortality represented an annual death-rate of 14.99, as against 16.42 in March and 15.09 in April, 1913. Among the diseases in which there was a diminished fatality were the following: The weekly average of deaths from diphtheria and croup declined from 46 in March to 40.5 in April; the weekly average from influenza, from 22.75 to 15.25; from epidemic cerebrospinal meningitis, from 4.5 to 3.75; from pulmonary tuberculosis, from 209 to 197.75; from acute bronchitis, from 19 to 15.25; from pneumonia, from 197 to 132.5; from broncho-pneumonia, from 145.5 to 116.25; from organic heart diseases from 238 to 208; from apoplexy and softening of the brain, from 28.5 to 24.75; from appendicitis and typhlitis, from 16.25 to 13.75; and from Bright's disease and acute nephritis, from 126 to 110. Among the diseases in which there was an augmented mortality were the following: The weekly average of deaths from typhoid fever increased from 2.5 to 3.75; from measles, from 17.5 to 20.5; from scarlet fever, from 13.5 to 18; from whooping-cough, from 5.75 to 7.5; from tuberculous meningitis, from 17 to 18; from cancer, from 79 to 87; and from hernia and intestinal obstruction, from 10.5 to 14.75.

REGULATIONS FOR RIVER BATHING.—The Board of Health has reconsidered its determination to prohibit river baths this season, but has adopted stringent rules and regulations for their control. Floating baths must be constructed with water-tight bathing pools and, where river or harbor water is used, this must be purified so as to render it clean and sanitary. Bathing beaches are not permitted within 500 feet from a sewer outlet and water-closet accommodations in connection with such beaches must be so constructed and maintained as not to contaminate the water used by the bathers. The department, it is stated, has obtained the willing coöperation of private bath owners and of the president of the borough of Manhattan in the application of the new rules.

ST. LUKE'S HOSPITAL.—The annual report of St. Luke's Hospital shows that last year 5433 patients were treated in the wards and 22,139 in the dispensary department. In March there were 833 ward patients, the highest record for a single month. Recently an auxiliary of ladies has been organized to enlarge the social service work which St. Luke's has been carrying on for the past three years, for the relief of its convalescents and out-patients. The aims of the auxiliary are to aid the physicians and surgeons of the staff by investigating and relieving the social conditions which hamper the patient's recovery, to confirm the cure by seeing the patient safely through his convalescence, and to safeguard the general health by spreading the educational influence of the hospital throughout the homes of the community. Many a discharged patient, it is stated, finds himself, in the early stage of his convalescence, without a cent of money and without a friend to aid; while many a mother, suddenly obliged to go from her tenement home to the hospital, leaves five or six little children uncared for all day—except perhaps by a girl of eleven or twelve—until the father's return from work at night. The auxiliary aims to look after such as these and many others, and to give intelligent and effective relief through its visiting nurses and social workers.

LEBANON HOSPITAL.—At the annual meeting of the managers of Lebanon Hospital, in the Bronx, held on May 17, the reports showed that during the past year 49,057 cases were treated at the hospital, and that 2888 ambulance calls were made. The cost of maintenance, including the training-school for nurses, was $165,268.

MORTALITY FOR THE WEEK ENDING MAY 16, 1914.—There were 1533 deaths and a death-rate of 14.32 per 1000 of the population reported during the past week as against 1531 deaths and a rate of 14.87 for the corresponding week of 1913, an absolute increase of 2 deaths, and a decrease of .55 of a point in the rate equivalent to a relative decrease of 59 deaths.

Measles showed a decrease of 11 deaths, diphtheria and croup 13 deaths, whooping-cough 2

deaths, digestive diseases other than diarrheal 15 deaths, organic heart diseases 2 deaths, pulmonary tuberculosis 26 deaths, Bright's disease and nephritis 9 deaths and violence 10 deaths. The following causes showed an increased mortality: scarlet fever 4, typhoid fever 4, diarrheal diseases 5, influenza 4, all other causes 68. The number of deaths from acute respiratory was the same as in 1913.

Viewed from the point of age grouping there was an increase of 17 deaths of children under one year of age, between one and five years of age there was a decreased mortality of 41 deaths; between five and sixty-five years showed a decreased mortality of 36 deaths, and at sixty-five years and over there was an increased mortality of 62 deaths, that is the mortality at the extremes of life was considerably increased, while that of children over one year of age and adults below sixty-five years of age evidenced a large decreased mortality.

The death-rate for the first twenty weeks of 1914 was 15.35 per 1000 of the population as against a rate of 15.56 for the corresponding period of 1914, a decrease of .21 of a point.

2. Voorsanger inclines favorably to artificial pneumothorax. He does not believe it is necessary to confine the patient to a hospital for treatment. Many of his cases are done in his own office or the patients' homes. Treatment should be checked by x-ray.

3. Clark advocates the single massive dose in the radium treatment of superficial epitheliomata. He thinks it will prove the method of choice as the dosage may be measured. The two great objections to its use are the cost and length of time of exposure.

5. Murphy, working experimentally on rats and chick embryos, finds that heteroplastic tissues grow in animals treated with the Roentgen ray, probably by the removal of the lymphoid barrier.

7. Corbus finds antigonococcic serum efficient in the treatment of gonorrhea and its complications. The complement fixation test is a reliable guide to its use as the intensity and efficiency of the two are in direct proportion. The amount should be from 36 to 45 c.c., administered intramuscularly, or from 12 to 15 c.c. a day for three days. Serum sickness, even if distressing, should not be alarming. A negative test after two or three months shows complete cure.

1. Howard's article on bronchiectasis is an able discussion of the etiology of the condition with illustrative cases. It is concluded that the condition is clinically not an infrequent one, being too often mistaken for pulmonary tuberculosis. The possibility of a foreign body or of syphilitic stenosis as etiological factors must always be considered. Inflammatory causes are the most frequent. As to the mechanism of production, the most plausible theory is that of Ewart, attributing the dilatation to the joint action of a faulty distribution of air space and bronchial obstruction.

3. Wilson reports further analyses of cases of goitre. His pathological evidence seems to show a constant relative association of increased secretion and increased absorption from the thyroid gland proportional to the degree of toxicity on the part of the patient.

4. Rowntree discusses the significance of the numerous tests of renal function which have recently come into prominence. He concludes that the phthalein test is the one most deserving of general application. When this reveals decreased excretory capacity, one of the blood tests, urea, total non-coagulable nitrogen, or serum cryoscopy, should be employed to determine the presence or absence of cumulative phenomena in the blood.

6. Knopf describes an improved apparatus for producing therapeutic pneumothorax in tuberculosis, and states concisely the indications and contraindications for this treatment. It is recommended in general for cases that have failed to respond favorably to general medical treatment, obstinate hemorrhage and bronchiectasis. The chief contraindications are extensive involvement of both lungs, much cavity formation, pleurisy, ascites or other abdominal distention, cardiac, renal or constitutional disease. It is not recommended in early and favorable cases.

7. Wood reports observations upon the manner of entrance of anthrax bacilli into the tonsil of the hog, showing that they penetrate only through the crypts, passing apparently through the living unaltered cryptal epithelium. [F. W. P.]

1. Mayo describes cases of chronic cholecystitis, especially those which he calls the "strawberry type" from the appearance of the lining mucosa of the gall-bladder, with an indurated condition of the head of the pancreas, which he believes to be evidence of chronic pancreatitis. In certain cases of this type treated by drainage of the gall bladder relief occurred, while the drainage persisted, but symptoms recurred as soon as the drainage was discontinued. He believes that removal of the gall-bladder is indicated, cholecystectomy in his cases having given prompt and permanent relief.

2. Ruhräh calls attention to the condition of pylorospasm in infancy in distinction to that of congenital hypertrophic stenosis of the pylorus. These disorders, while similar in their manifestations and perhaps related in their etiology, differ in that the pylorospasm is accompanied by less violent symptoms, is of much better prognosis, and does not always appear immediately after birth. In treatment he emphasizes the necessity of the use of breast milk, and speaks favorably of the giving of atropine in 1-2000 grain doses every four to six hours.

5. Goodman describes cases in which the blood-pressure is found to be subnormal, particularly in association with symptoms of neurasthenia. In a number of these improvement was effected by treatment, after which the blood-pressure was found to have increased. This treatment consisted chiefly of general tonic measures, such as gymnastic exercises and hydrotherapy, which are given in detail. Drug treatment played little part, although some reliance is placed upon strychnine.

6. Nicholson urges that greater attention be devoted to the observation of diastolic as well as of systolic blood-pressures, the former being now readily determined by the auscultatory method. He also describes a portable mercury sphygmomanometer which he has devised, less bulky than those in common use.

8. Krumbhaar and Musser report a series of 149 cases in which the Moro percutaneous tuberculin test by inunction of a tuberculin paste in lanolin was applied. The tendency to react positively in cases clinically not tuberculous, which has caused the von Pirquet test to be discarded for use in adults, was little in evidence, since in 76 unselected non-tuberculous cases only 5 failed to give a negative reaction, and in only 2 was the reaction definitely positive. Of 44 tuberculous cases all reacted positively with the notable exception that of 10 cases of far advanced pulmonary tuberculosis 9 reacted negatively and 1 doubtfully positively, a finding consistent with the results of other tuberculin tests in advanced tuberculosis. It is concluded that the prevalent opinion that positive reactions in adults are of little or no value is erroneous.

10. Farr and Williams find that in normal pregnant women the total non-protein nitrogen does not usually exceed 30 mg. per 100 c.c. of the whole blood, but may reach 40 mg. or more without demonstrable renal lesions. In all of their cases in which there was definite renal insufficiency or eclampsia, with one exception, there was always a slight, and in most cases, a marked, increase in the total non-protein nitrogen, similar in degree to that found in parenchymatous nephritis, but less than that found in interstitial nephritis. The retention, however, bore no relation to the severity of the symptoms, and its significance is regarded as inferior to that of rising blood-pressure albuminuria and the general clinical picture.

13. Bond urges a closer scrutiny of insane patients for evidence of pituitary disorder. In 1600 consecutive autopsies on insane patients, lesions of the pituitary body were found in 45, and in a brief survey of the inmates at one time of the Danvers Hospital 10 cases with suggestive symptoms were found.

14. Barnes reports experience with graduated exercise in pulmonary tuberculosis similar to Patterson's auto-inoculation method. While he regards this treatment as advantageous where it can be carried out without inducing symptoms, and as of value as a test of the patient's fitness to return to work, he warns against the belief that fever reactions or auto-inoculations are other than harmful.

15. Janeway has analyzed the first symptoms of 21 cases of cancer of the esophagus, finding that dysphagia is not by any means always the first to appear, and that in a small minority only was the diagnosis made before three or four months after the patient had symptoms. [F. W. P.]

1. The writers conclude that the gold test is essentially a laboratory method requiring extreme care in preparing reagents and cleaning of glassware. Normal fluids give normal reactions; the test has no value in purulent or tuberculous meningitis, and has no advantage over known laboratory methods in diagnosing syphilis. Reactions are inconstant in secondary and tertiary stages; positive reactions observed in the majority of cases of tabes and cerebrospinal syphilis are not characteristic, while the reaction peculiar to paresis seems to be of some value in differential diagnosis.

2. Sellards states that the essential feature of acidosis consists in a general impoverishment of the body in bases or in substances which readily give rise to bases. The fundamental features of every acidosis as thus far established are: (*a*) an increase in the tolerance of the body to fixed bases, (*b*) a diminution in the titratable alkalinity of the body serum, and (*c*) a diminution in the carbon dioxide of the blood. An acidosis of high grade occurs in certain nephropathies, especially in the uremia of acute and chronic diffuse nephropathy. It is not a terminal event and is often present in relatively high grade outspoken cases many months before the development of the uremia. It represents the effect rather than the cause of the renal lesions. [J. B. H.]

1. Pasteurization in bottles is a safe and easy process, provided the temperature is maintained within the bottle a sufficiently long time. The one drawback to this method is the expense of water-tight caps, which are necessary. To avoid this the milk is first pasteurized and then, while hot, is poured into bottles which have just been steamed for two minutes. This process is safe, inexpensive and easy. In this way bottle infection is eliminated and the ordinary cardboard caps may be employed. The bottles are air cooled. The sole disadvantage of this method is the loss of time in those plants where milk is delivered directly after pasteurization.

5. Aqueous solutions of methyline blue of fuchsin show very slight bactericidal power. Such solutions of gentian violet, however, are markedly bactericidal to gram-positive organisms, even in very weak solutions. Anilin gentian violet and carbol fuchsin, as made up for staining, show a decided disinfectant action upon cover glass preparations. This action is due to the stain, especially in the former case; mice controls, controls consisting of dried, fixed, but unstained preparations, showed organisms in the subcultures. No such bactericidal action was produced by laboratory methyline blue. Those facts are of practical importance to laboratory workers. Mice slides and cover glasses may in some instances, but not in others, be handled with safety, according to the stain employed. [L. H. S.]

1. Ormerod, in this first Lumleian Lecture, discusses in a general way hysteria, its relation to neurasthenia, its symptoms, such as hysterical fits, anesthesia, hysterogenic zones, contractures, skin affections, edema, wasting, ecchymosis, et al.

2. Watson, describing the various clinical manifestations of intestinal toxemia, believes that treatment is largely medical and in the earlier stages it can be cured if medical treatment is efficiently carried out. In advanced cases, however, surgical intervention seems to offer the only hope. X-ray examination is essential to arrive at a proper diagnosis. Lane's short circuiting operation is simple, but in inexperienced hands is often unsatisfactory. Before any operation a prolonged course of medical treatment is advisable. [J. B. H.]

7. ELLIOT, R. H. *The Experiences of Surgeons in Sclero-Corneal Trephining.*
8. BLACKLOCK, B. *On the Multiplication and Infectivity of T. Cruzi in Cimex Lectularis.*

1. Davies believes that those cases of phthisis suitable for artificial pneumothorax are: (1) those with a persistent fever, (2) profuse or repeated hemorrhage, and (3) cases with cavity formation. He describes in detail his technic, and among complications mentions pleural reflex and gas embolism. He is in favor of frequent refillings at first and of keeping up the treatment for at least eighteen months. He discusses immediate and remote results, the value of other forms of treatment, tuberculin, exercises, etc., in conjunction with nitrogen treatment. He also speaks of this treatment for bronchiectasis and putrid bronchitis. There are some excellent plates.

6. Symes presents evidence which is fairly conclusive showing the close connection between erythema nodosum and tuberculosis, although he believes that in certain forms at least the disease is a distinct clinical entity. [J. B. H.]

5. MCINTOSH, J. *Critical Review: Anaphylaxis and Its Bearing on Medicine.*
6. SIMONS, I. *Critical Review: Bacterial Endocarditis.*

1. Four cases of paroxysmal tachycardia are reported, with histological examination of the heart in three of them. The latter confirmed the clinical diagnosis, which was based on the study of electrocardiograms and of venous tracings. In the first case the extra-systoles appeared to be of ventricular origin, for the auricular rhythm was undisturbed and the form of the extra-systoles differed from that of beats of supraventricular origin. At the autopsy a marked lesion was found in the interventricular septum, consisting of fibrosis involving two-thirds of the thickness of the wall. The second case was clinically, judging from the shape of the beats in the electrocardiogram and the presence of an auricular wave in the venous tracing, a paroxysmal tachycardia of auricular origin. At the autopsy there were found a well marked infiltration with lymphocytes and two small hemorrhages in the region of the sino-auricular node. The a-v node and bundle were intact. In the third case, also of auricular origin, there were perivascular lymphocytic infiltrations about the sino-auricular node.

2. McNee reviews the recent work on cholesterin in the blood and tissues, including some interesting studies of his own. The cholesterin content of the blood is increased in a number of conditions, *e.g.* Bright's disease, diabetes, jaundice, adiposity, arteriosclerosis and pregnancy. Where the amount in the blood is too large the cholesterin of the bile is increased also. Hence the relation of pregnancy, and adiposity, to gall-stones, especially the solitary stone of pure cholesterin, which, as the researches of Aschoff show, may arise without inflammation. These facts also explain the association of exanthemata, in which the cells are stuffed with cholesterin, with diabetes and chronic jaundice; also the "white spots" in the retina, which consist of cholesterin, with Bright's disease and diabetes.

3. The Mikulicz syndrome consists of bilateral painless swellings of the salivary, and sometimes of the lachrymal glands. It is sometimes associated with enlargement of the lymph nodes and spleen, with or without the blood changes of leukemia. Thursfeld's case was remarkable for the rapidly fatal course and the blood picture, that of an "aplastic" anemia with marked decrease in the leucocyte count and lymphocytosis. He calls it aleukemic leukemia.

4. Kemp examined the hearts of a large number of cases of acute articular rheumatism two years or more after they left the hospital, to determine whether the murmurs heard were due to organic disease of the valves, or to mitral insufficiency resulting from myocarditis. The results confirm the statements of Romberg and others that myocarditis is a frequent cause of such murmurs, for 22% of the cases developed signs of carditis, which disappeared during convalescence, and in 20% of those who showed signs of endocarditis not clearing up before discharge from the hospital, a later examination showed the heart to be quite normal. Only 22% of the total number showed no signs of cardiac disease throughout the acute attack. [W. T.]

1. Neubauer has introduced creatinin as a test for renal function. Normally, creatinin is formed from endogenous protein destruction and thus the amount excreted is nearly constant without regard to the diet. Neubauer considers that this fact makes the excretion of the substance a valuable test for renal function, since patients to be studied require no special diet, and can be observed when they are up and about, as well as when they are in bed.

To make the test, the creatinin excretion is followed every four hours for three days. On the second morning a test meal is given which contains 105 gms. of the pure substance dissolved in sugar-water. Normally it is excreted almost immediately. With diseased kidneys, its excretion is delayed in proportion to the degree of functional disturbance. For the differential diagnosis between marked passive congestion and true nephritis, the test is of as little value as are most of the other tests based upon the excretion of physiological substances. Marked disturbances of creatinin excretion occur with congestion as well as with nephritis. Finally, in advanced nephritis, creatinin accumulates in the blood significantly, and parallels the retention of nitrogen and urea.

13. Beck reports, on account of its rarity, two cases of nutmeg poisoning which occurred in two of the hospital servants. Two women prepared a drink of nutmeg, cinnamon and wine, and after taking it, remained in a comatose condition for a considerable period. Both recovered. The mixture was taken by one to induce abortion, and by the other to make a diagnosis of early pregnancy, since she had been told that nutmeg would induce menstruation in the event of lacking pregnancy.

Beck reviews the literature on the subject of the toxicity of nutmeg. It has been used in the cases reported to induce abortion, and has produced the symptoms of stupor which were seen in Beck's cases. The pharmacological basis for its supposed action appears to be the fact that its oils in enormous dose cause congestion of the abdominal and pelvic organs. [R. F.]

2. Larbé and Bith.—*Amino-aciduria Provoked by the Ingestion of Peptone and the Diagnosis of Hepatic Insufficiency.*
3. *Debré and Paraf. *"The Antigen Reaction" (Completed).*

3. The conclusions which Debré and Paraf draw from the present and previous articles upon the use of a complement-fixation reaction upon tubercular fluids are of great value. The reaction is specific in a very high percentage of cases when performed on the urine secreted by kidneys, affected by almost any variety of tuberculosis,—whether granular, ulcerative, or even amyloid. Such reactions are not present in the urine from healthy kidneys even of individuals suffering from pulmonary tuberculosis. Similar reactions have been performed with great success in pleural and abdominal fluids, whether serous or purulent. The application of the test to cerebro-spinal fluids and blood sera has not been productive of very constant results. Its use in sputum is encouraging and deserves further trial. [L. H. S.]

1. *Ravà, G. *So-Called Paralytic Oculo-Cephalic Deviation from Lesion of One Cerebral Hemisphere.*

1. Ravà reports and discusses 16 cases presenting the symptom-complex described in his title. He believes that such deviation is not solely dependent on the paralysis, but is determined by the activity of healthy sensory centres not counterbalanced by corresponding activity of injured homologous sensory centres, principally those of vision. [R. M. G.]

Miscellany.

MEDICAL STATUS OF THE UNITED STATES ARMY.

In the current issue of the *Engineering Record* is an article by Dr. William C. Gorgas on army camp sanitation. The following extract may serve to represent the opinion of the surgeon-general on the medical status of our troops in case of possible war in Mexico.

"In the event of an invasion of a sub-tropical country by our army the sanitary precautions to be observed by our troops would be of supreme importance. Our precautions must, however, begin at home in our assembly and concentration camps. In the war with Spain in 1898 we were handicapped by lack of training and experience

in camp sanitation. We had practically no experience in the tropics. The great development of preventive medicine was not then in a stage convenient for practical application.

"In any contemplated occupation of a country lying partly in the tropics by an army coming from the temperate zone there would be two stages to consider with reference to the precautions necessary to the preservation of the health of such a command—first, the measures required to avoid the "camp diseases" in the homeland while the troops were mobilizing and training and second, the measures required to avoid the diseases peculiar to the country to be occupied. The first sanitary precaution is to secure healthy soldiers—physically sound men. Then it is necessary to safeguard their health while in training by giving them pure food, water and healthy camp surroundings and by preventing the entrance to such camps of infectious diseases.

"When we have to deal with the question of potable water in the enemy's country, and especially in the field, we deal with a more difficult problem, but by no means a hopeless one. Efforts are made to ascertain the quality of the water by examinations and by its reputation when that is practicable. When deemed necessary—and this is the case with all surface waters in the tropics, unless we except some mountain streams—we try to render the water safe for drinking purposes by such measures as may be possible in the field. However, it will often occur that under military stress, lack of time and transportation, troops for short periods must use the water that the natives depend upon. Under these circumstances we may look for the appearance of such diseases as are water-borne and are prevalent in the communities using the water. The methods to render the water potable are naturally those used in temporary emergencies as a rule—boiling, filtering and the use of chemicals. Portable appliances are used in the army to render the water safe.

"Only less important than a supply of potable water in camp is an efficient method for the disposal of human wastes. Excreta in camp become a most dangerous focus for the dissemination of such diseases as are spread through this means by direct contamination or pollution of water and milk and by flies. In the last large camps maintained by the army in Texas in 1911 and 1913 a most efficient system was used. On still larger scale but for a shorter time the same system was in use at the Gettysburg reunion in 1913. For a year in the Texas camps this system has given complete satisfaction.

"Flies spread typhoid, dysentery and perhaps other diseases. It is necessary, then, to devise a method of gathering and destroying both stable sweepings and kitchen wastes. In camp the army has disposed of this by burning the sweepings after they are gathered at a dump and by burning right at the kitchen door the wastes therefrom. Moving troops in the field, as a rule, have no trouble with the disposal of these wastes, as they are so scattered that the amount constitutes no menace.

"In such an army as might be mobilized for service abroad we would expect some 120,000 regulars, and twice as many volunteers. There will be, therefore, a considerable proportion of green men to be taught camp sanitation, as well as given military instruction. Much of this will be given in concentration camps. There exists a yeast to leaven the whole that was absent in 1898. Since that year the officers of the medical department of the army have been studying and practising military hygiene and sanitation with brilliant results, as demonstrated in the two large camps in Texas. Here ten thousand men lived for a year at a time with sick rate lower than that at the average post. The army, then, is in an entirely different position from that at the outbreak of the Spanish War.*

"Anti-typhoid inoculation which has been in vogue in the army since 1909, and which so efficiently protected it in 1913 that there was but one case among the inoculated in the army of 90,000, is to be trusted to keep our camps free of this disease so fatal to armies of the past. The dysenteries will be held in abeyance by many of the precautions that prevent typhoid, particularly the safeguarding of water and the early exclusion of such cases from the camps. Yellow fever is robbed of much of its terror by the fact learned in 1898 by Reed and his devoted band, which taught us the means of transmission and, consequently, the manner of avoiding it. One other disease, typhus fever, we have learned, is spread by the bite of the louse, and, in consequence, we are enabled to limit its ravages.

"Thus, forewarned, we are forearmed and enter any campaign confident of our ability and in the sanitary training of the line to feel that we can exist in the campaign in a state of "hygienic competence" that the disabilities of the war will be limited, for the first time in the history of the New World, to wounds, and that disease will not kill more than bullets. The American people will have what they should have for the generous support given every year—the most efficient army of its size in the world."

* [During the Spanish War of 1898, 20,000 cases of typhoid fever occurred among our soldiers in the field or in camps.—ED.]

CANCER MEETING IN BOSTON.

AT the invitation of the Boston City Federation the American Society for the Control of Cancer held a public meeting for the discussion of the cancer problem at Huntington Hall, Boston, on Tuesday afternoon, May 19. Similar meetings have recently been arranged by the Cancer Society in New York, Chicago, St. Louis, Pittsburgh and other cities.

The meeting was under the auspices of the Boston Federation of Women's Clubs. Since the

meeting was held on the same day as the opening session of the annual meeting of the American Gynecological Society, when many visiting physicians were in Boston, it was possible to secure speakers representing a widely distributed experience, who discussed the various phases of cancer with an unusual degree of authority.

The president of the Boston Federation of Women's Clubs, Mrs. Frank L. Young, opened the meeting as chairman, and Dr. Edward Reynolds, vice-president of the A. S. C. C., introduced the first speaker, Frederick L. Hoffman, LL.D., statistician of the Prudential Life Insurance Company of America and chairman of the committee on statistics of the A. S. C. C., who presented the evidence of "The Prevalence and Increase of Cancer in the United States." The work and purposes of the American Society for the Control of Cancer were described by Dr. F. F. Simpson of Pittsburgh, Pa., one of the founders of the Cancer Society and a member of its executive board. Dr. J. Collins Warren of Boston, a trustee of the Society, discussed the cancer problem from the point of view of the Huntington Cancer Commission of Harvard University of which he is chairman.

The second half of the meeting was devoted to a symposium of public education on cancer in which a number of physicians of recognized authority in their special fields indicated what the public should know about this disease in order to avoid its suffering and mortality. Among these five minutes' addresses were the following: Dr. Mixter of Boston spoke on cancer of the digestive organs. Dr. Walter W. Chipman of Montreal discussed cancer of the breast. Dr. Howard C. Taylor of New York discussed uterine cancer, and Dr. David Cheever of Boston described the symptoms and treatment of external cancer.

The need of public education and the social aspects of the cancer problem generally were summarized in a brief address by Rev. Dr. George A. Gordon who closed the meeting.

Correspondence.

PARIS LETTER.

THE MEDICAL ATMOSPHERE OF THE RENAISSANCE, AS PORTRAYED IN SOME EARLY FRENCH WRITERS.

I. PHILIPPE DE COMMYNES.
(1490, Circa.)

(From Our Special Correspondent.)

PARIS, April 16, 1914.

"Dixisse me aliquando penituit, tacuisse nunquam."

(Inscription on the wall of the dungeon at Loches, ascribed to Ph. de C.)

Mr. Editor: In a former letter (January 9, 1913) I dwelt at some length on the medicine of the 17th century in France, as revealed in Molière's "Malade Imaginaire" (1673), and on how man's substratum of plain commonsense *will* come to the fore and protect him, in spite of all that perverse thought and erroneous doctrines can accomplish toward his undoing: *e.g.* the course of treatments applied by Dr. Purgon, and the friendly advice of the level-headed brother: sager counsels could hardly be preferred even at the present time than those of Béralde.

But if we go further back still, to the early times of the Renaissance, and examine the leading writers of the day, we again find a similar state of affairs: on the one hand what we can scarcely call anything else than sheer folly, in medical circles, acceptable to a certain number of panic-stricken patients; and on the other, the part of the population which (even in a state of illness, as in the case of Montaigne) looked on the question from a practical and sensible standpoint, and refused absolutely to be duped by the errors and superstitions of the practitioners of the epoch.

There are among the interesting old writers of that period, three who stand out preëminent in this respect,—Philippe de Commynes, our excellent confrère François Rabelais, and Michel de Montaigne, and I think that a brief exposition of their views on medical matters may not prove devoid of instruction. If I were to take these authors in their order of interest, that incomparable master of good-humored satire, Rabelais would unquestionably be entitled to precedence. But it will be best to treat them chronologically, and in this respect Commynes comes first, his classical Mémoires dating from the end of the 15th century, just about the time of the discovery of America, to be exact.

This book is one of the chefs d'oeuvre of French literature, as can be imagined when I say that after a lapse of over four centuries it still reads as easily as a novel and is said to be, after the Holy Scriptures, one of the works that has been re-issued the oftenest. Philippe was the intimate friend and counsellor first of Charles, Duke of Burgundy, and then of three kings of France in succession, Louis XI, Charles VIII and Louis XII; but it is chiefly with the reign of Louis XI (1461–1483) that he deals, and his portrait of this ruler is the standard on that subject. Whether we consider his remarkable delineation of the political atmosphere of the day, his power of description, his astounding memory *ex post facto* of the entangled threads of intricate negotiations, or his philosophical reflexions as to the difficulties of being King in this world,—all is equally absorbing; and at the same time the quaint old French in which the narrative is couched adds manifestly an element to the story, as *we* see it, that must of course have been lacking to readers of the times, although Montaigne, who wrote nearly a century later, and who refers in his Essays to the works of both Rabelais (who came between the two) and Philippe, speaks of him in the most flattering terms, toward the end of Chapter X, Book II.

Not among the least interesting of de Commynes' characteristics is his implicit faith in Divine Providence and evident conviction of the presence of a personal guiding-hand in all matters, public or private, as well as of his, Philippe's, ability to see the action of this hand and detect its purpose. The fashion in which Philippe carries his Providence, as it were, about with him in his breast-pocket, and brings it in whenever called for, despatching the believer, no matter how sinful, to paradise, and the infidel, no matter how deserving, to sheol, is really remarkable, on the part of one of the most prominent and capable men of the day. For instance, in referring to the death of a certain Turkish prince he remarks: "en cecy ne parle point dudit Turc, car je tiens ce point pour vuidé et qu'il est logié avecques ses prédecesseurs." This comes pretty near to the doctrine of the Wahabees, who are reputed to claim that the world is divided into 73 religious sects, of which theirs alone is destined to salvation.

Philippe has left no actual discourse on medical matters, as did Montaigne and Molière; but he was more

or less mixed up with the end of several very prominent men, and in particular of Louis XI, and was in this way led to chronicle various doings and sayings that throw light on the medical customs of the times, although so far as he personally was concerned, his clear intellect appears to have enabled him to take a rational view of medical matters and to estimate the science of his day at its true value.

Taking up, then, first the case of Louis XI,—this sovereign had an initial stroke of apoplexy in March, 1480, a second one the year following, and his final illness in August of 1483,—a total duration of three and a half years. Louis was an unusually authoritative man, even for those days, had his way in all matters, and exacted implicit submission from everyone connected with him; and in particular the historian remarks that "by nature he was disposed not to place faith in the advice of physicians." But he also says: "never did man fear death so greatly,"—so much so that he constantly directed those about him, in event of illness, to be careful what they said to him, to advise him merely to confess himself, and not to make use of the word death. Yet observe the irony of Fate! This domineering spirit, that doubted his physician's word, and lived in terror of death and all connected with it, was finally forced to place himself implicitly in the hands of his intimates, became terrorized by his medical attendant whom he placated by the payment of large sums of money, and finally had his death-sentence served to him in such a brutal manner as to draw forth the indignation of even such a moderate and reserved man as the historian.

Commynes was away at Argenton, his château, when the first stroke occurred near Chinon, and it is a curious coincidence that he was likewise absent in the same manner when Charles VIII had his cerebral hemorrhage at Amboise. However, he describes the event evidently from the account of the spectators, and we have here in a few lines an exact tableau of what practically always takes place when a medical catastrophe strikes one of a group of laymen, who with this apparently irresistible human impulse to be doing something, although utterly ignorant of the elements of the proposition, find it impossible to refrain from making a bad job worse, and seem the more determined in their misguided efforts in proportion to their lack of intelligence. Could anything be more descriptive of this state of mind than Commynes' half dozen lines: "at dinner he was seized with a stroke and lost the power of speaking. He was removed from table and kept near the fire, with the windows closed; and although he made every effort to get to them, his companions prevented him (acting for the best, as they thought)." So much for that part of the scene, now comes the complement, the arrival of the medical man. He, naturally, has also to appear to be doing something; but as it would never do to let the laymen think they had acted correctly, the man of art usually orders the opposite to what has already been done; sits the patient up, if he had been laid flat, gives him air, or water, if these have been witheld, and so on: "Thereupon you arrived, who were his physician at that time, and at once gave him an enema and opened the window to let in the air." Now if this whole scene is not the neatest little piece of irony on the classical performance on such occasions, then I confess to being grossly mistaken.

Little by little speech began to return to the royal patient, whose first act was to unburden himself to his confessor who had been summoned from Tours, although, as the historian remarks, "he had not very much to say, as he had already confessed himself a few days previously, because, when the Kings of France wish to lay hands on those afflicted with scrofula, they first go to confession, and our King never failed in this (laying on of hands) once every week. If the others (kings) do not do this, it is a great pity, as there are always plenty of sick people." We are here, consequently, right in the heyday of those fortunate times when organic disorders yielded to the contact of divine right! Being now in a state of grace and filled with the milk of human kindness, Louis' next act was the following. He inquired and ascertained who were those that had restrained him by force on the occasion of his stroke; these he at once drove from his court, taking from some of them their positions and dismissing them once and for all, while from others he took nothing but sent them off. "Many were astounded at this action, which they criticized adversely, saying that they had acted for the best, and so they had"; but Louis was so in fear of anyone venturing to infringe on his rights, even with the purest of intentions, that nothing of this sort could be tolerated.

If now we turn to his final illness, August, 1483, which lasted from Monday to Saturday, we find ourselves in the presence of a very different man. Louis is now broken in spirit, suspicious of everyone, in terror of death, and placing his last hope in holy men and physicians. And here again we have the usual tableau of such occasions: the infinite hoping against hope, "for notwithstanding his misfortunes his courage rose and he quite expected to recover"; truly Aeschylus never had a deeper thought than when he made Prometheus take away from mortals the power they once had of foreseeing future events, and gave them in its stead *blind hope*,—observe the force of the qualifying adjective,—hope in spite of anything, everything and everybody, what would life be without hope,—an unthinkable nightmare.

The other characteristic of such crises is the feeling of hate toward the medical attendant; when the patient finally comes to the realization that his end is near; when *their* life is at stake the man of science ought to be able to arrest the flight of time, to change the order of the seasons, and to reverse the orbits of the celestial bodies. Connected with this frame of mind is the thought, generally felt, sometimes openly expressed, that if the medical attendant would only give himself the trouble, a remedy could be found! To gain this end no means is too vile. With Louis it took the form of bribes: "his physician, Maître Jacques, in whom he had complete confidence, and to whom he gave 10,000 'escus' each month, in the hope that he would lengthen his life and that he would bear his case constantly in mind, setting aside all other thoughts." Maître Jacques may have had other patients as ill or even more so; these were all to be dropped, because the royal patient *had the money to pay!* This is a condition of spirit not unknown in our own day with a certain type of mind, witness the following anecdote: One of our very wealthy and very well-known society women was ill with a self-limited disease at one of the very swell hotels in Paris where she was attended by a very fashionable doctor. The whole matter was, as you see, quite an extra-special performance! The disease was running its usual course without incident, but the patient could not understand how such a thing could be, with a person of her importance; this was all well enough for hospital patients, but for *her!* So she finally made the following epic speech to the medical attendant: "but doctor, why do you not give me something to break up this disease and stop it short; you *must* have remedies that will do this, *which I can pay for but which others cannot.*" The more one reflects on that creature's mentality,—and she is a very important person and no fool,—the more astounding does her remark become.

But to return to Maître Jacques, who appears to have been quite a character for the day, and whom we can perhaps look on as the prototype of a kind of physician existing also at the present time, the man who without any particular medical merits retains his patients' allegiance by a process of "bulldozing," if you will pardon the term. During the last five months of Louis' life this artistic confrère extracted from his august charge "fifty thousand écus in hard cash, the bishopric of Amiens for his nephew, as well as other positions and properties for himself and

friends." Now when we consider the difference in the value of money between those days and ours, and if I am correct in estimating the écu at three francs, you must agree with me that for a poor sinful mortal that doctor didn't do so badly by himself and relations! The historian proceeds: "The said doctor was so very rough with him that no one would say to his valet the offensive and rude words that he used; but the King stood so in awe of him that he did not dare to discharge him. The King complained concerning him to those around him, but he would not have ventured to change him as he did all his other servants for the reason that the said doctor used to fling the following taunt impudently in his face: "Je scay bien que ung matin vous m'en envoyrez comme vous faictes d'autres; mais par la . . . (ung grant serment qu'i juroit), vous ne vivrés point huyt jours aprés!" Isn't that simply lovely?

Finally this mighty ruler who had always lived in such awe of death that he had time and again desired his intimates never to speak of it, but, when the time came, to resort to subterfuges, to "go easy," as the expression appears to mean (parlés petitz), had his death warrant flung in his face in the following cavalier fashion. Having observed that the king continued to shut his eyes to facts, in spite of the gravity of his condition, three members of his immediate circle, one of whom was our distinguished confrère Dr. Jacques, decided that the truth must be made known to him, and laid the situation unmistakably before him in the following terms: "Sire, we must fulfil our duty; cease hoping in this holy man (a hermit he had sent for from the far end of Italy) or in anything else, for of a certainty the game is up; on this account make your peace with God, since of remedies there is none." That is what might be called the delicate and finished touch, in the way of breaking bad news, and even the historian's sentiments were outraged, since he remarks: "he had raised these men, suddenly and without grounds, to a condition to which they were not fitted; therefore they did not hesitate to say to such a ruler things that were out of their province, also failing to observe the reverent and humble attitude suited to the case." When this little joint speech had been delivered "each one said a few brief words," to which this impenitent optimist replied: "I have hopes that God will help me, since peradventure *I am not as ill as you suppose!*" Not long subsequently the king expired,—as so commonly happens with people who have particularly apprehended their latter end,—peacefully, without suffering, fitted with the necessary sacraments, and conversing with those about him concerning the arrangements that he wished carried out at his funeral!

Louis XI has led me to such lengths that I shall have to make short work of the other medical details in our author. Charles VIII, his successor, struck his head against a beam in a doorway, and succumbed in nine hours, probably to meningeal hemorrhage. This occurred on the eve of "pasques fleuries," the pretty term for palm Sunday. The account was given to Commynes by the King's confessor who during the preceding week had on two occasions had the King at confession one of them on account of those who came to him for scrofula—as was likewise mentioned in connection with Louis. Commynes goes on to say that the disorder was apoplexy and that the physicians hoped that it would only affect one arm and not carry off the patient. "He was attended by four good physicians but only trusted the craziest of the lot, to whom he accorded so much authority that the others did not dare to speak, although they would gladly have purged him four days previously, as they thought they detected indications of death,—which actually came true." These must have been very far-sighted practitioners indeed.

Another interesting passage in Commynes is that in which he tells of the neurasthenic condition into which fell Charles, the iron duke of Burgundy, after his terrible rout at the hands of the Swiss at the battle of Morat,—and of the treatment of this disorder. He says: "he worked little, and kept to himself, and seemed to do so more from obstinacy than from any other cause, for his grief was so great as to upset his mind, so that he became seriously ill. For whereas his natural temperament and bodily heat were so great that he could not stand wine, but in the morning usually took some "ptizanne" and eat rose-conserve to freshen himself up, this grief changed his disposition in such a way that he had to be put on strong wine undiluted; and in order to get the blood back to the heart, they placed burning tow in dry-cups, and applied them thus heated to the cardiac region." This treatment of such a common trouble as neurasthenia may appeal to some inquiring mind.

In this connection (and also on another occasion) Commynes speaks of the advisability in cases of great adversity of acquiring relief by unburdening the soul to others: "It is of the greatest service to confer with special friends, and not to be afraid to manifest one's distress . . . since this relieves the heart and cheers it up and one's spirits revive." The other instance refers to Louis XI in his illness: "on no occasion did he complain, as do all kinds of persons in trouble, at any rate that is the sort of man *I* am, and I have seen many others act in a similar manner, since to lament is said to relieve suffering.' This is, of course, a well-known fact of current observation.

A visit to the donjon prisons of Loches, where Louis used to keep his particular enemies in safe guardiance, raises some curious medical points. One of the very original features of this institution was that the royal gaoler, not satisfied with shutting his prisoners up in dungeons cut out of the solid rock, in some cases altogether without light, had had constructed solid cages, 8 feet by 8 by 7, out of rectangular bars of oak strengthened by iron inside and out, into which he would pass a victim and then have the cage swung up in the air to a beam. Cardinal de la Balue, for instance, is reported to have spent three years of his long captivity in such a cage; and even Philippe de Commynes relates that under Louis' successor he personally was shut up in one for eight months.

Still other prisoners, besides those kept in ordinary dungeon chambers with no light and air but what could penetrate through one of the slits in the 4-5 metres thick wall, in the cages, and in caves with no light whatever,—were confined by an oak grating in the window-aperture itself; their space, then, would be in the form of a wedge, whose point was the outside window slit, its sides the thickness of the wall, and its base the opening into the dungeon barred by the oak grating. Thus, one very distinguished captive, the Duc d'Alençon, is reported to have passed five years in such a predicament at Loches.

Now the interesting question is this. Those prisoners were mortals like ourselves. They were mentally fulgurated, besides being inadequately clothed and fed. They had no light, little air, and no heat; in particular, the situation of the prisoners in those window-cells must have been trying to the extreme. Yet they seem to have survived it,—in fact Philippe refers to his little experience in terms that are almost jocose. Speaking of the inventor of these cages he says: "Many are those who have cursed him, among them myself, who have 'sampled' one of them for eight months, under the present king." It would appear that the men of those times must have been made of very different stuff from ourselves.

There is one piquant detail, in connection with these dungeons and torture-chambers, that can hardly be omitted. Louis XI was very devout; a man who could act with such ferocity as that was pretty sure to be pious,—*that* could have been told in advance. Under the church up in the fortifications of Loches is a subterranean chapel where he was accustomed to perform his devotions, and in particular he was in the habit of praying there for the souls of the prisoners he was about to submit to torture! From this chapel runs an underground passage that ends,—in the dungeon where de la Balue hung in his bird-cage,

and d'Alençon was enclosed in his icy window-aperture! The King could thus pay them a little private visit, now and then, and gather their personal views as to things in general! These rulers were not styled protectors of the true faith without very just grounds, evidently.

"S."

ITALIAN QUINTUPLETS.

BOSTON, MAY 18, 1914.

Mr. Editor: The newspaper clipping attached hereto gives the information that Rosa Corrada gave birth to five children at one parturition and that all are enjoying the best of health.

Inasmuch as we seldom hear of quintuplets being born, I thought it might be well to report this apparently authentic case.

Yours truly,

GAETANO PRAINO, M.D.

CINQUE FIGLI IN UNA VOLTA.

Palermo, 15.

Un fatto che si assicura non ha alcun riscontro s'è prodotto in questa città. Certa Corrado Rosa, metteva alla luce in un sol parto cinque figliuoli.

Puerpera e neonata godono ottima salute.

SOCIETY NOTICES.

AMERICAN MEDICAL EDITORS' ASSOCIATION.—The American Medical Editors' Association will meet on June 22 at the Marlborough-Blenheim Hotel, Atlantic City, N. J., under the presidency of Dr. E. A. VanderVeer of Albany, N. Y.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—The annual meeting will be held in Room 125 of the Copley-Plaza Hotel, Boston, on Tuesday, June 9, 1914, at two o'clock.

Preceding the meeting, the annual lunch will be served in Room 123 at 1.30 o'clock.

Annual reports and election of officers.

The following papers will be read and discussed:—

1. "The Relation of the Industrial Accident Board to the Medical Examiner," Mr. Edward F. McSweeney, Member of the Massachusetts Industrial Accident Board.

2. "Poisoning by Paris Green," Theodore S. Bacon, M.D., Associate Medical Examiner, of Springfield.

3. "The Murder of Captain Charles D. Wyman of the Barge *Glendower*," George Burgess Magrath, M.D., Medical Examiner, of Boston.

OLIVER H. HOWE, M.D.,
Recording Secretary.

Cohasset, May 20, 1914.

APPOINTMENTS.

SYRACUSE UNIVERSITY.—*Dr. Oliver W. H. Mitchell* has been appointed assistant professor of bacteriology.

UNIVERSITY OF MISSOURI.—*Dr. E. R. Clark* has been appointed professor of anatomy, and *Dr. Mazyck P. Ravenel* professor of preventive medicine.

RECENT DEATHS.

DR. CHARLES T. WAINRIGHT, of New York, died from cardiac disease at Englewood, N. J., on May 7. He was a native of Lewis County, Mo., and 56 years of age. Dr. Wainright was graduated from the Missouri Medical College in 1882, and afterwards studied for a considerable time in Europe. In 1889 he received the degree of M.D. from Bellevue Hospital Medical College, New York, also. He was appointed professor of internal medicine at the University Medical College, Kansas City, Mo., and after serving for several years resigned to accept a similar position at the New York Post-Graduate Medical School. For some time before his death he had been incapacitated by ill health.

DR. WILLIAM EDMUND WEBER, of New York, died suddenly on May 7, at the age of 47. He was graduated from the College of Physicians and Surgeons, New York, in 1891, and since 1896 had served in the New York City Health Department. For the past four years he had had charge of the work of the infants' milk stations of the department. Dr. Weber was also attending physician to the out-patient department of the German Hospital.

DR. JOHN ALEXANDER FITZ-HUGH, a Fellow of The Massachusetts Medical Society, died at Amesbury, March 21, 1914, aged 59 years.

DR. THOMAS M. L. CHRYSTIE, of New York, died on May 19, at his country home at Rye, Westchester County. Dr. Chrystie was a lineal descendant of Major James Chrystie of the New York troops in the Continental Army, and was a hereditary member of the Society of the Cincinnati. He was born in 1841 at New Windsor, on the Hudson, where the family had been early settlers. He was graduated from Trinity College, Hartford, in 1863, and served for a time at the Cavalry Corps Hospital of the Army of the Potomac. He was then transferred to the navy, and was acting ensign on the staff of Admiral Farragut until the close of the war. He was graduated from Bellevue Hospital Medical College in 1867, and later became attending surgeon to the New York Orthopedic Dispensary and Hospital. For the past twenty-five years he had been surgeon of the New York State Branch of the Society of the Cincinnati.

DR. DANIEL MORRIS WOOLLEY, of Brooklyn, died from cancer of the liver on May 18. He was a native of Deal Beach, N. J., 64 years of age, and was graduated from the Medical Department of New York University in 1885.

DR. JOSEPH E. A. LANOUETTE, who died of septicemia on May 16, in Manchester, N. H., was born at Champlain, Que., in 1850. He graduated in 1872 from University Bishop College. From 1873 to 1881 he served as a surgeon in the Canadian militia. He was for many years a member of the local board of health.

CANCER OF THE UTERUS.

THE POSSIBILITIES OF CURE BY THE RADICAL ABDOMINAL OPERATION. CERTAIN ORIGINAL METHODS OF OPERATING. INCLUDING AN ANALYSIS OF 367 CASES AT THE MASSACHUSETTS GENERAL HOSPITAL.

By Farrar Cobb, M.D., Boston,

Visiting Surgeon to the Massachusetts General Hospital.

This paper is substantially the same as that read at the clinical meeting of the Staff of the Massachusetts General Hospital, February 20, 1914. The paper should be of value from an educational point of view because,—

(a) It gives a complete analysis, from the standpoint of end results, of all the cases of cancer of the uterus at the Massachusetts General Hospital for fourteen years, from 1900 to 1913 inclusive, 367 in number, of whch 70 were my own personal cases.

(b) It emphasizes the importance of early diagnosis of cancer of the cervix and distinctly shows the possibilities of cure by the extended abdominal (Wertheim) operation, and describes certain original methods of operating which are of importance.

In 1912 I published an article on the same subject,[1] analyzing the hospital cases from 1900 to 1910 inclusive and it is only natural that the present paper should be related to the first in form and substance.

In preparing this article opportunity has been given me to prove previous work and review conclusions in the light of three additional hospital years and my own larger operative experience and to describe in detail some original technical methods which I have developed. Those who have read my previous paper will recognize doubtless certain statements and opinions and for such inevitable repetition I crave indulgence.

It is a plain duty to study our own end results and compare them with those of other workers the world over, and this applies particularly to special workers in different fields; but while our results must be compared with those of the best workmen anywhere, it is not fair to compare the results of a large number of men, some of whom have had no special training or experience, operating intermittently with relatively small material, with the work of one well trained man who has worked continuously with abundant material. This should be considered when we compare our results as a whole with those of Wertheim or with the results of one of our own number who has been given more opportunity and material.

I have been interested in the radical abdominal hysterectomy for cancer of the cervix since 1901 and up to January 1st last have done this operation 29 times, with an immediate mortality of 4 or 13.7%, 25 cases in the hospital and four cases during the last year in my private practice. Two cases have been done too recently to be included in this analysis. Only the hospital cases will be included in this paper. Previous to August 1, 1911, the operations at the hospital were done by many surgeons including myself. Since that date, under the present system of assigning special lines of work to individuals, all the cases of cancer of the uterus have been operated on by me.

By radical operation I mean substantially that done by Wertheim, which, concisely, is the removal of the uterus and a liberal portion of the vagina through a median abdominal incision with thorough dissection of the ureters and bladder and the removal of as much of the parametrium as possible, the regional lymph glands to be removed only if palpably enlarged. It is a difficult and tedious operation and the profession and the public should be made to understand that it should be done only by specially trained men. Surgeons who are jealous of their immediate mortality records should not operate for cancer of the cervix; one must disregard absolutely his surgical reputation, as far as his primary results are concerned, for the sake of curing more patients in the future.

I believe there is urgent need for education on the subject of cancer of the uterus; education of medical students and the medical profession; education of surgeons and of the lay public, and that until a vigorous campaign has been waged for a long time, the majority of women with this disease will continue to be deprived of their proper chance of life, as, beyond question they have been in the years that are past. It is not unusual to hear men of wide surgical experience say that the abdominal operation for cancer of the cervix is unjustifiable, because of the small chance of ultimate cure and the extremely high immediate mortality. In fact, since I began my special work at the hospital in August, 1911, more than one of my distinguished colleagues on the Staff have expressed practically the same opinion. Such teaching is to be condemned; men holding such opinions do not know what has been accomplished. As stated by Dr. William P. Graves in his admirable discussion of my first paper, "It is unquestionably true that the prognosis of cancer of the cervix operated on early by a trained surgeon employing the best technical methods is considerably better as to recurrence than that of an early cancer of the breast operated on under similar circumstances, and the surgical treatment of cancer of the uterus is

par excellence Wertheim's extended abdominal operation."

When you consider that over three-fifths of the patients presenting themselves at the hospital with cancer of the cervix come too late for any attempt at a radical operation, and of those radically operated on by surgeons not specially experienced probably three-fourths will die inside of five years,—and our analysis at this hospital proves this,—it is little wonder that physicians and the laity believe it to be an incurable disease. The two most important questions in relation to this subject are,—

1. How can we teach the public and the medical profession the importance of early diagnosis and the possibility of cure?

2. In what cases is a surgical operation justified?

In the fourteen years from 1900 to 1913 inclusive, 367 cases of cancer of the uterus were admitted to the hospital, including cases of cancer of the cervix and cancer of the body of the uterus. Seventy of these were my personal cases. Cancer of the uterus usually means squamous cell cancer of the cervix. In discussing the radical operation and the late results the cases of cancer of the cervix have been separated from those of the body of the uterus, since cancer of the fundus is a comparatively favorable form for cure by simple hysterectomy, either vaginal or abdominal.

Cancer of the cervix is a disease demanding a radical operation. Wertheim's reported cases are all cancer of the cervix. The important part of my work from an educational point of view relates to this form.

One great lesson from such a large series of cases, the work of many men, is that there is great need of an effective system of completing hospital records, from the standpoint of end results. The difficulties in securing final information in this large number of cases have been great and the hospital records, with the exception of the last few years, have furnished practically no help. I cannot help feeling a certain amount of satisfaction at the result of our labors in that out of 103 cases surviving the operations of hysterectomy of all kinds 93, or all but 10, have been traced. I have not lost track of any of my own cases.

Wertheim's latest report covers a period of fifteen years from 1898 to 1912. His work during this period should be compared with our hospital results from 1900 to 1913, fourteen years. Of our 367 cases:—

4 refused operation.
57 were considered inoperable.
173 had a palliative operation, either amputation, or curetting and cauterization, with or without ligation of the internal iliac arteries, (this last procedure only being done since I began this special work.)
17 vaginal hysterectomies.
116 abdominal hysterectomies.

At the end of my paper I will give a tabulated review of the statistics of the cases in detail.

230 cases came too late for a radical operation, an operability of only 36.2%. According to Wertheim's latest statistics 50% of his cases were operable. From 1898 to 1912 he examined 1430 cases.

71 refused operation.
684 were inoperable.
675 had a radical operation done.

The appalling lack of operability is due to popular ignorance as to the nature of the disease and its hideously insidious onset, and also to the neglect of medical practitioners to examine the cases or to recognize the importance of the conditions found on examination, and also, and this applies especially in this country, to the lack of knowledge on the part of surgeons as to what is an operable case. The operability at this hospital is about the same as at other hospitals in this country.

Since August 1, 1911, I have had personally 50 cases of which 5 were inoperable; 23 had palliative operations, including eight cases in which the iliac arteries were tied; radical abdominal hysterectomy was done in 22 cases, an operability of 40.4%, too small a number of cases and too small an increase in operability to justify any conclusions as to the value of our specializing in educating the community. It should be realized that for years in Germany a publicity campaign to educate the laity has been carried on and it is gratifying to note that something is beginning to be done in this country in this direction. Until we can teach convincingly that irregular bleeding at any time in a woman's life may mean cancer, and always demands investigation by a competent man, we will continue to have an appalling list of hopeless cases and avoidable deaths. Every medical society in every city and town should be aroused to the serious need of such education and the importance of a thorough examination.

EARLY SYMPTOMS.

Our series of cases simply corroborates what is already known, that the commonest early symptom is irregular bleeding; that pain is a late symptom, but our statistics in regard to the first symptoms and the duration of symptoms are of small value because of inaccurate observation on the part of patients and the failure to make careful notes in the majority of the records. In the 230 inoperable and palliative cases the average duration of symptoms before the patient came to the hospital was about one year. Undoubtedly cancer of the cervix may be present for many months before any symptoms are noted. It may go to an inoperable stage with practically no symptoms and still such cases live for years. One case came to the hospital three weeks after the first

symptoms were noted and was thought to have inoperable disease and yet lived for four years and eight months. The average duration of life in the cases that were not operated on at all was between seven and eight months, whereas the average duration of life in the palliated cases was thirteen months. It is interesting to note here that one case of adeno-carcinoma of the cervix is alive and well without recurrence at the end of eleven years after a palliative operation; *i. e.*, amputation with the cautery.

I make here a plea for those unfortunate patients who come too late for radical operation. I think it is our duty in every case where a radical operation is inadvisable to make determined and repeated efforts toward the prolongation of life and relief of pain and hemorrhage. I feel sure that all too frequently the operable cases here and elsewhere are neglected and allowed to die without much of anything being attempted for their relief. We are all familiar with the value of thorough curetting. It should be remembered that curettage without the use of the cautery is unwise and that the cautery itself probably has a positive influence in checking cancer growth much deeper than the surface actually cauterized. In other words, there is hardly any doubt that the developmental activity of the cancer cells can be arrested and permanently destroyed at a distance far remote from the surface upon which the cautery is used. Recently Dr. James F. Percy, Galesbury, Ill.,[2] has exploited at medical meetings and in journals his exaggerated use of the cautery in inoperable cases. He uses a water-cooled vaginal speculum, puts a thermometer in the bladder and opens the abdomen so that he can detect a dangerous amount of heat. His statistics are not convincing and we must wait a number of years before passing comparative judgment upon his method of the use of the cautery.

Between cauterizations much good can be done by local applications, either of acetone or formalin. The value of radium emanations is uncertain, but in cases in which this treatment can be obtained it should be tried, not neglecting general treatment, bromide of arsenic and tincture of iodine, and the judicious use of opium, in accordance with the principles laid down by Dr. George W. Gay.[3]

I have in eight cases supplemented the curetting and cauterization by opening the abdomen and ligating both internal iliac arteries. I first thought this procedure was an original one with me, but have found out since that it originated with Charles Ryall, Surgeon to the Bollingbrooke Hospital and the Cancer Hospital of Bromptom, England.[4] He reports over twenty cases of ligation with decided benefit and no complications. There has been no immediate mortality in my eight cases and in certain of them I have been much impressed by the almost instant relief from pain and hemorrhage. Patients that before operation have required morphine in fairly good sized doses have needed none the day after. The operation is one that can be done rapidly and safely even in obese patients. The abdomen is opened by a median incision, both ovarian and both internal iliac arteries tied with silk and the abdominal wound closed without drainage. Obviously, the theory of this method is to shut off the blood supply to the uterus and by starving the malignant growth diminish pain and hemorrhage. The two of my cases that most strongly illustrate the value of this procedure are:

Case 1. Hattie A., Hospital No. 182694.

This case illustrates *also* what, in my opinion, is a wrong way to deal with cancer of the cervix. She entered the hospital first in May, 1911. An assistant surgeon curetted and cauterized the growth and the patient was discharged with the advice to return in a month for radical operation. In my opinion, the radical operation was indicated at this time, and should have been done within a week or two after the cauterization, if not immediately following. The case teaches us that women should not be allowed to go out of the hospital without a radical operation. This patient got so much relief from the curetting and felt so well that she did not return until May, 1912, one year after her preliminary curettage; too late. She had had almost constant flowing for three months and much pain in the right lower abdomen, travelling down the right leg. An abdominal incision revealed marked involvement of the parametrium on both sides and extension of the growth into the broad ligament, most marked on the right, where a loop of the small intestine was adherent to the disease. This was not freed. The internal iliac arteries were tied with silk. Hemorrhage ceased at once and the pain practically disappeared. She left the hospital in very good condition June 1, 1912. I saw her at intervals of a month at the hospital and at her home in East Cambridge. She had no return of the hemorrhages and remained quite free from pain until six months before her death, which took place Oct. 9, 1913, a year and four months after ligation, a case that could have been radically operated on when it first came into the hospital. Final symptoms were markedly relieved by ligation.

Case 2. Annie S. Hospital No. 185890.

Carcinoma of the cervix and extensive pelvic metastases following palliative operation fifteen months before in another city. Very severe pain for weeks, requiring large doses of morphia. In November, 1912, I ligated both internal iliac arteries. She had immediate relief from pain and required practically no opiates after operation. Before operation large doses were repeated during the day. Required no opiates the last week of her stay in the hospital. The patient is still living, but at present in very poor condition.

WHAT IS AN OPERABLE CASE?

Two hundred and thirty cases of the hospital series were pronounced unfit for radical operation, but this represented the opinions of many different surgeons. It

is probable that some of the cases regarded by some of the men as beyond surgical aid, might have been considered by others as fair risks. The fact that of the 317 cases before August, 1911, only nine were given the advantage of an exploratory laparotomy proves to me that in many a true decision could not have been made. If the entire pelvis is filled with a hard mass, the uterus fixed and the vagina markedly involved, there is no doubt but that such a case is inoperable, but in many cases no bimanual examination, with or without an anaesthetic, can determine positively that the case is not one for radical treatment, because fixation of the uterus and indurated masses in one or both broad ligaments are not infrequently due to inflammatory tissue, adhesions, pus tubes or cysts. Even if fixation and induration in the broad ligaments is due to cancer, such cases should have the advantage of exploratory laparotomy because it is certain some of the apparently desperate cases, even those involving the bladder, can be cured. Of Wertheim's cured cases there were no less than ten that had been considered inoperable by very worthy men. In nine others the wall of the rectum was involved and in six others the bladder was so fixed that its loosening was very difficult. In several others the parametrium was so widely infiltrated that in separating it from the pelvic wall it gave the operator the impression that he was cutting through cancerous tissue. One of my own cases that had lived the longest free from recurrence; namely, thirteen years, was a case in which the left ureter had to be dug out of a mass of apparent disease and in which the iliac glands on both sides were markedly enlarged and were removed. This is the case of Elizabeth C., W. S., vol. 369, page 120. In her case there was marked thickening and induration in the left broad ligament noted before operation, and one case, in which the uterus was fixed and both broad ligaments indurated, is alive and well over five years. I have operated on three cases operated on palliatively by other men. In each case I found it possible to do a radical operation; in two of them the bladder was opened and successfully repaired. One died of recurrence, one year, eight months and nine days afterwards; the other two are cured. Therefore, in the face of such evidence as Wertheim's and my own limited experience, I believe that there are a number of cases in which none of us have the right to decide in regard to the possibility of a radical operation until the abdomen has been opened. The borderline cases will be the most difficult, possibly involving injuries or resection of the bladder and ureters, but without operation death is certain, suffering extreme, and we know that with it a definite number of cases are cured. Cystoscopy may give some evidence in regard to the extension of the growth to the vesico-cervical septum. If there is a prominence of the trigone, it is an indication that this area is involved, but even if the cystoscope should show probable invasion of the septum, it would not be positive proof and a radical operation even then, with resection of the bladder, might not be impossible. If on exploring a case it is found unfit for a radical operation, the valuable palliative operation of tying the iliac arteries can be quickly done.

The general condition of the patient must be considered carefully in deciding upon the operation and a long, tedious and frequently bloody abdominal operation should never be attempted in feeble subjects; it is contra-indicated, also, in the presence of marked adiposity. In such cases vaginal hysterectomy should be substituted. In certain of the adipose cases it may be possible to do a para-vaginal or radical vaginal hysterectomy, the operation of Schuehardt and Schauta, as will be described in detail later. My experience has convinced me that the Wertheim operation in very fat women is one of extreme difficulty and great risk to life, and in the future I will avoid the operation as much as possible in such cases and intend to do the extended vaginal operation. One of my fatal cases was that of a very fat woman in whom a vaginal hysterectomy was impossible on account of the inability to pull down the uterus because of firm intra-abdominal adhesions subsequent to a previous laparotomy. Death resulted from general peritonitis. During the time Wertheim was doing 500 abdominal operations he performed vaginal hysterectomy only 21 times, in 5 cases for high-grade adiposity, in 11 cases because of cardio-renal disease, in 5 cases of very early cancer diagnosed only by the microscope.

CARE IN PATHOLOGICAL EXAMINATIONS.

Unless great care is used, pathological examinations of tissue from the suspected cervix may be in error. The most favorable cases for cure are those in which the diagnosis of cancer is made early by the microscope. Possible sources of error are depending upon curetting without excising pieces, failure to obtain tissue from the diseased area, and incomplete study of the tissues after removal, also the mixing up of specimens in a laboratory which is burdened with much work. In suspicious cases wedge-shaped pieces should be cut from more than one place, should involve the area of granulation tissue under suspicion and the normal mucosa adjoining. Many sections should be cut and examined with care. Great pains should be taken to prevent the mixing up of specimens with those from any other case. As an illustration of the possibility of error, there were three cases in our series in which no operation was done because the pathological reports were in one case "blood clot," in two "simple glandular hypertrophy."

These three cases died of typical cancer of the cervix clinically. In one of my cases it is certain that the specimen was interchanged with that from another case in the laboratory.

I have done two cases in which the pathological report was non-malignant after operation, one case was a sloughing fibroid and the other arterio-sclerosis. These cases both recovered, but have not been included in my series of radical operations for cancer of the cervix. In the operation for sloughing fibroid the bladder was badly torn and a large vesico-vaginal fistula persisted for many weeks; finally I was able to close this.

IMMEDIATE MORTALITY AND RESULTS.

Since writing my earlier paper nearly two years ago, I have had opportunity to trace cases then classed as untraced and to prove and correct my statistics. Before analyzing our own cases I will give you Wertheim's latest report on his percentage of cures by the abdominal method. By his report of November, 1912, he had done the radical operation 675 times, 380 were done over five years previous to the report, and of this number 160 cases were cured, over 42%. His immediate mortality in the first ten cases was 30%, and in his last 175 only 9%, a most striking illustration of the possibility of improving one's technique and results by practice.

VAGINAL HYSTERECTOMIES.

In our series there were 17 vaginal hysterectomies, 13 for cancer of the cervix and 4 for cancer of the fundus. The immediate mortality was zero. 14 operations were done over five years ago, and of these 8 were traced. 2 cases were cured, both of them cancer of the cervix, 25% of cures in the vaginal operation for cancer of the cervix. Since 1910 there were 3 cases, all of which are free from recurrence from one to three years, 2 cancer of the cervix and 1 cancer of the fundus. It is interesting to note that there were no cures in cases of cancer of the fundus, which is supposed to be but slightly malignant and for which the operation of vaginal hysterectomy is justifiable.

I believe it is true that the simple vaginal hysterectomy in the hands of numerous men who have had no special training or experience will be the safest method and give a greater percentage of cures than the radical abdominal method in the *same hands*, but I believe most earnestly that cancer of the cervix should be operated on only by men specially educated and trained. After the studied results of special operators in this and other countries and our own cases, as shown here tonight, it must be admitted that simple vaginal hysterectomy can have no place as the operation of choice for cancer of the cervix except in very fat subjects and in those cases where it is wise to do a rapid and comparatively safe operation because of the poor condition of the patient and possibly in a small number of cases of very early microscopic diagnosis. No operator with large experience has been able to report over 10% of cures.

We should, however, compare the radical vaginal or paravaginal operation of Schuchardt and Schauta with the radical operation of Wertheim. Briefly, it is an operation in which the vaginal wall and labia on the left and all the para-vaginal and para-rectal tissues are split to the sacrum laying wide open the perineum. By this procedure it is possible to remove a generous portion of the vagina and some of the parametrial tissue, but it is said to be difficult and bloody and undetected injuries of the bladder, rectum and ureters are common. The danger of implantation metastasis is greater and the lymph glands cannot be reached. Its immediate mortality is almost as high as Wertheim's and the percentage of cures not so large; convalescence is often complicated by tedious suppuration and sinus formation.

ABDOMINAL HYSTERECTOMIES FOR CANCER OF THE FUNDUS.

There were in our series 27 cases in which seven cases were my personal operations. The immediate mortality was 4 or 14.8%. Of the surviving 23 cases I have traced 22, of which 14 were operated on over five years before. Six of these cases are cured, or 42.8%. In addition, one case is free from recurrence 4½ years and one 3¼ years. In my personal cases, 7 in all, I have had no immediate mortality and but one death from recurrence; this case was far advanced and in very weak condition when I operated and the disease had extended to the peritoneal surface of the body of the uterus.

It is a matter of surprise to me that the percentage of cures of carcinoma of the fundus, both by the vaginal and abdominal route is so low. Dr. Graves in his discussion of my previous paper stated that the figure for non-recurrence should be as high as 90%, while the primary surgical mortality should be practically nothing. The only explanation of our immediate mortality, 14.8% by the abdominal method with only 42.8% cured cases, is the fact that a few of the cases came to operation in an advanced stage of the disease in poor condition. A case of this sort is my case, Zenia C., No. 190040, who died with recurrence in the liver four months and nine days after operation.

ABDOMINAL HYSTERECTOMIES FOR CANCER OF THE CERVIX.

Total number 89; squamous cell 87 and adenocarcinoma 2. I have divided the abdominal hysterectomies into two groups, the simple, not radical, operations, 49 in all, and the radical,

40 in number. By simple hysterectomy I mean the removal of the uterus with no extraordinary attempt to dissect the ureters and remove the parametrium widely. Radical hysterectomy is substantially Wertheim's operation.

Of the 49 simple hysterectomies there was the excessive immediate mortality of 17, or 34.6%. Of the surviving 32 cases I have been able to trace 29. Of these 26 were operated on over five years ago, cured only 5, or 19+%. In addition, two cases are free from recurrence from three to four and a half years. Of the 40 radical hysterectomies there was an immediate mortality of 9, or 22.5%. Of the surviving 31 cases I have traced all the 31, of these 14 were operated on over five years ago and 7, or 50% are cured.

Of the 40 radical hysterectomies 23 were done by myself. Of the 17 cases not done by myself all were traced, the immediate mortality was 5, or 29%. Of the 12 surviving cases, 8 were operated on over five years ago. One case is cured, 12½%. In addition, two cases are alive and free from recurrence over three years. Of my own 23 hospital cases, the immediate mortality was 4, or 17+%. Six cases were done over five years ago, 5 are cured. In the cases since August 1, 1911, 17 in number, I have so far four recurrences; three cases are free from recurrence from one to two years. The cause of death in the abdominal hysterectomies in the majority of cases was septic peritonitis; shock was the next most frequent cause.

In reviewing the hysterectomies certain features are worthy of special note. Simple vaginal hysterectomy was the safest in the hands of a large number of operators and gave a larger percentage of cures than simple abdominal hysterectomy by numerous surgeons. The simple abdominal hysterectomy, with an immediate mortality of over 34%, proved to be an extraordinarily dangerous method in the hands of various surgeons and its percentage of cures is very small, not sufficient to justify its employment as an operation having any advantage over vaginal hysterectomy. Cases in which the bladder, rectum or ureter were injured were far more common in this set of cases than in the radical operations. We are led to conclude that the abdominal operation which makes no attempt to dissect the ureters and remove the parametrium, to say nothing of the glands, cannot be advocated as a safe or reasonable operation for cancer of the cervix, because such an operation exposes the patient to increased danger from shock, hemorrhage and peritonitis without making any more effective removal of the disease and its lymphatics, than in a simple vaginal hysterectomy.

The 40 radical hysterectomies including my own cases show an immediate mortality of 22½%. The cures were 50%, a showing which speaks for itself as satisfactory. The lower mortality and increased percentage of cures by the radical method can be explained by the fact that these operations were attempted only by two or three men specially interested and educated, whereas, the majority of the simple hysterectomies were done by many surgeons, most of whom, in all probability, had made no special study of the technique of the subject, or, chose the abdominal route as a method with which they were more familiar.

The important factors in the operation are:

1. The preliminary preparation.
2. The anaesthetic with special reference to the prevention of shock.
3. The abdominal incision.
4. The freeing and handling of the ureters.
5. Removal of the parametrium and glands.
6. Control of hemorrhage.
7. Prevention of peritoneal infection and implantation metastasis from the growth itself.
8. Drainage and after treatment.

I gradually have adopted some original technique by which I think the operation is made even more radical and perhaps somewhat safer. I refer specially to the combined method of spinal and general anaesthesia, the abdominal incision, the retraction and elevation of the ureters by tapes and the ligation of both internal iliac arteries.

PRELIMINARY PREPARATION OF THE PATIENT.

Under this heading is to be considered the general preparation of the patient, the getting her into the best possible condition for the operation, and also the preliminary preparation of the vagina. Special attention should be paid to the condition of the heart and kidneys; the functional renal test should be done with care more than once. A percentage of 25 prohibits the radical operation. It has been surprising to me to see how much certain cases have improved in ten days or two weeks by rest in bed, forced fluids and liberal diet with a moderate amount of stimulation. This had been especially so in a number of cases of adeno-carcinoma of the body of the uterus; women quite advanced in years, cases which on entering the hospital seemed to be inoperable because of the irregular pulse and feeble condition, and upon which a successful hysterectomy was done.

I wish to say here that the combined method of spinal and ether anaesthesia has enabled me to safely operate on a number of cases which previously I should not have operated upon, or, if at all, under the feeling that death would almost certainly result. I will take up this method of anaesthesia in detail later on. More so than in any other pelvic operation, the presence of distended coils of intestines will seriously interfere with the technique. At least two days of light diet and catharsis are needed.

It is impossible to make any hard and fast rule in regard to the preparation of the vagina. Wertheim usually curettes and cauterizes the

growth on or about the cervix immediately before beginning anaesthesia for the abdominal operation. He does this usually without anaesthesia, and claims that the patients suffer little pain. This is hard to believe. The difficulty of getting sufficient relaxation without anaesthesia, to say nothing of the psychic shock to a woman facing such an ordeal, would contraindicate any such proceeding. I have come to believe that in the majority of cases it is best to do the curetting and cauterizing, if it is necessary, and the disinfection of the vagina as the first step of one operation, and to do it under combined anaesthesia, and, as I will mention in discussing anaesthesia, the vaginal part can be begun immediately after the first injection has been made, while the ether is being started.

I have found that curetting and cauterization as a distinct preliminary operation a week or ten days before the abdominal operation is apt to create a much more foul and septic condition about the cervix because of the large migration of bacteria into the freshly infiltrated areas, and also, I believe that the formation of scar tissue in the cauterized areas where the cervical growth has been large will tend to make the intra-pelvic freeing of the bladder and the rectum much more difficult. In cases where the cervical growth is small and confined to the cervix, where I am sure that I can at the later stage of the abdominal operation go far down the vaginal walls with the right angled clamp, I do not curette or cauterize, simply disinfect the vagina as described below. The cases of extensive proliferative growth are curetted and cauterized, after which the vagina is disinfected. The only cases in which I think it best to do curetting and cauterization as a distinct operation a week or two in advance, are the cases that are in bad condition because of excessive hemorrhage, and cases which are flowing profusely on entering the hospital. In such it is wise to thoroughly curette and fire locally and wait a sufficient length of time to get the patient strong enough for the abdominal work.

To disinfect the vagina, whether or not the curette and cautery have been used, I use the following method. The preliminary preparation is always done by myself. After scrubbing with green soap and water, and using a 1-2000 corrosive douche freely, the scrubbing and corrosive douche being done before the use of the curette and cautery, I fill the vagina with tincture of iodine and allow it to remain two minutes. After wiping this out with gauze sponges the vagina is filled with alcohol, pains being taken afterwards to wash out all the alcohol with bichloride solution 1-2000. A small gauze sponge is tucked lightly for a short distance in the vagina as the final step, no attempt being made to demark the cervix or to attach any instrument to the posterior vaginal vault.

ANAESTHESIA.

The time necessary to do an operation of this magnitude will be from one to four hours. My quickest operation, in which I did not remove the iliac glands, required one hour and fifty minutes. My difficult cases have taken from two and a half to three and a half hours. It goes without saying that much pains should be taken to shorten the time in every way and that the choice of anaesthesia and the anaesthetist is of the greatest importance. The chief cause of death following this operation are shock and septic peritonitis.

Spinal anaesthesia has been done in 33 cases by Wertheim, either with stovain or tropacocaine. In general the duration of the anaesthesia possible by the spinal method alone is too short for the performance of this operation, and the necessity of using a large amount of the interspinal fluid in combination with the Trendelenberg position tends to make this method of anaesthesia dangerous. In addition, I believe it to be very important to have the patients, who almost always are in fear of the operation, unconscious and oblivious to the manipulation and surroundings.

Ether has been accepted as the best anaesthetic. In my paper published a year and a half ago I said it was the only anaesthesia to be considered. I still think so,

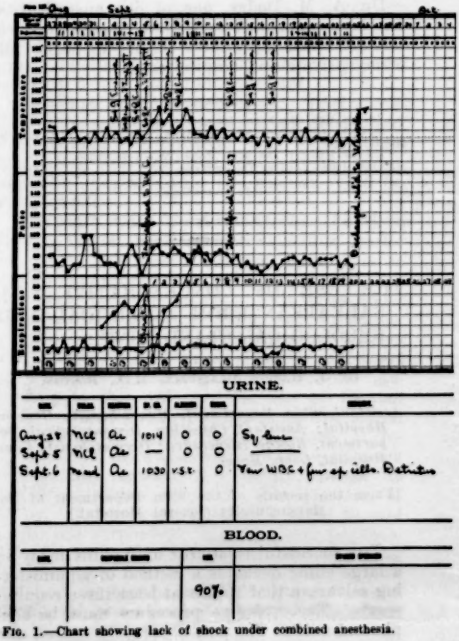

Fig. 1.—Chart showing lack of shock under combined anesthesia.

but I have found in the last eleven months that by using spinal injection and ether in combination that not only have I had no shock at all or anything approaching it, in most of the cases, but the patients have been free, in a most surprising degree, from the alarming sequelae and complications of convalescence that all too often cropped up in the cases leaving the operating table in moderate or severe shock after a long etherization. This spinal injection is used as a "nerve bloc" on the anoci principle, or nerve blocking theory advanced by Crile; the idea being to shut off the nerve irritation from the extensive manipulation in the pelvis from the higher centres by using a moderate dosage of stovain or tropacocaine and in addition to secure unconsciousness and prolonged anaesthesia; ether is begun at once after the spinal injection and continued to the end of the operation. Figure 1 is a copy of the chart of one of the hospital cases illustrating the entire absence of shock in the pulse curve and the very satisfactory convalescence in these cases.

As I have said, the preparation of the vagina can be undertaken almost immediately. Half an hour before the anaesthesia, morphine gr. ¼ with atropine gr. 1-120 is given hypodermically. The spinal injection is from 1 to 2 c.c. of tropacocaine, 5% with suprarenin. (The 5% tropacocaine-suprarenin Lösnug made by G. Pohl of Germany.) This is given usually between the second and third lumbar vertebrae.

Dr. A. M. Dodge, one of our anaesthetists has been interested and kind enough to give this combined anaesthesia for me in nearly all of my private and hospital cases.

THE USE OF CONCENTRATED NEOSALVARSAN FROM A CLINICAL AND SEROLOGICAL STANDPOINT.

BY J. HARPER BLAISDELL, M.D., BOSTON,

Assistant, Skin Department, Massachusetts General Hospital; Assistant Physician, Dermatological Department, Boston Dispensary; Dermatologist, Lynn Hospital, Lynn, Mass.

[From the records of the Skin Department of the Massachusetts General Hospital.]

THE successful treatment of syphilis today in a large clinic demands a method of administering salvarsan that fulfills at least three requirements. The operative procedure must be simple and swift. The patient must be spared any immediate or permanent sequelae of a disabling nature. The disease must be checked as effectively by this as by any known method.

The use of concentrated neosalvarsan satisfies the requirements of simplicity, swiftness and freedom from objectionable after-effects as no other method has done. Therapeutiely, its true place can be settled only after the accumulation of much more data than is available at present.

After experimentation with mechanical holders and tubing devices the method of administration of concentrated neosalvarsan in the Skin Out-Patient Department of the Massachusetts General Hospital settled on the following simple procedure which has been successfully used without exception over three hundred times.

All the injections of the morning are mixed in one bottle which may be kept tightly corked. 20 c.c. of freshly distilled sterile water are allowed to each dose and that amount is poured into a small graduate. A straight needle with a Swift holder is introduced into the vein and as soon as the blood returns freely through the needle, the syringe is filled, quickly adjusted to the needle and its contents injected. The time consumed in the actual injection of the solution is about thirty seconds. All the operating is done under the strictest aseptic precautions. With the aid of one assistant or nurse to get the patients prepared, in position on the operating table and tourniquetted, a dozen injections have been given in less than an hour without undue haste.

This procedure, although simple in description and in operation, may present several points of difficulty to the novice in this method of injection. When the syringe is full, it is advisable to grasp the barrel well toward the upper end in order that the little finger may rest firmly on the plunger. Otherwise, if only the barrel is held and the syringe is tilted in the transfer from the graduate to the needle the weight of the plunger forces the fluid out at the end or if the position is reversed the plunger falls out entirely.

Another point to be borne in mind is that the syringe must invariably be adjusted to the needle and not the needle to the syringe. This is the most difficult part of the technique and the source of the greatest trouble in the whole operation. The syringe and needle combined represent the long arm of a tremendously powerful lever in comparison to the very short arm represented by the length of the needle within the lumen of the vessel. For instance, in the average injection the length of the needle in the tissue is about half an inch and the length of the rest of the needle and the filled 20 c.c. syringe is about ten inches. The firm skin at the point of injection acts as an excellent fulcrum. In as much as pressure applied at the long end of a lever increases in direct proportion to the length of the short arm it will

be seen that an eight ounce pressure on the syringe increases to a ten pound pressure at the end of the needle within the vein. This physical law explains in large measure the rupture or leaking of blood-vessels after the needle has apparently been successfully introduced. A steady hand to hold the apparatus as motionless as possible is an important requisite for the successful use of this method.

The concentrated neosalvarsan injection is splendidly adapted for use in the office or out-patient clinics where it is of primal importance that sequelae shall not interfere with the patients' unassisted return home or to work without considerable loss of time. In three hundred and forty-one (341) injections done in the Skin Out-Patient Department from November 10, 1913 to January 17, 1914 no patient found it necessary to recuperate in the recovery rooms because of untoward symptoms. As for illness for the twenty-four hours following injections, it was the exception for the patient to make any comment on the next visit about unpleasant sequelae. In the majority of cases it took searching questions by the phyician to bring to light symptoms that might be classed as after effects of the medicine. Dizziness, headaches, and diarrhea were commonly recorded, their occurrence being most frequent following the initial injection and in those patients where nerves and alcohol played a leading role. The evidence showed conclusively that the danger of unpleasant or dangerous sequelae when the injection is given by an experienced operator and under aseptic conditions is reduced to a minimum.

Broadly speaking, the success or failure of any method of medication depends upon its lasting therapeutic efficiency, irrespective of the facility it may be given by the physician or received by the patient. This test the concentrated neosalvarsan has yet to undergo and the results must be conclusively in its favor if it is properly to displace the original Ehrlich product, the worth of which is established in fairly definite lines.

Symptomaticly, the concentrated neosalvarsan is as active as any of its predecessors. Primaries disappear, rashes fade, mucous patches heal, headaches cease, and gummata resolve as rapidly as with the old salvarsan. It is only when the serological results are considered that doubts about its comparative value begin to arise.

In order to get a more definite notion of the serological side of the question it was proposed to take as many fresh untreated syphilitic cases as possible within certain time limits, give a series of four injections of concentrated neosalvarsan of a 0.45 gram dosage to each at weekly intervals and follow this by a Wassermann test one week after the last injection. Out of a series of sixty-two (62) cases, carefully selected and instructed as to the importance both to themselves and to their physician of carrying out instructions, only twenty-four (24) fulfilled the simple requirements of this five weeks course of treatment. The Wassermann tests in all instances were done with two antigens, the beef heart extract and the new cholesterinized heart extract. The details of the series of cases were as follows:

For practical consideration this series can be divided into three fairly distinct groups,—ten cases of early syphilis, four cases of late secondary manifestations, and ten cases of late syphilis. It is to be regretted that Wassermann tests were not done on all cases before treatment but it seems fair to assume that as the positive diagnosis of syphilis was made the Wassermann would be as strong before treatment as after.

Group I. Ten cases. *Cholesterinized antigen.* One stronger after treatment than before. Eight unchanged or strongly positive after treatment. One changed from strongly positive to weakly positive. *Beef heart antigen.* Five became less strong after treatment. Five became negative.

Group II. Four cases. *Cholesterinized antigen.* One remained strongly positive. Three became less positive. *Beef heart antigen.* One remained weakly positive. Three became negative.

Group III. Ten cases. *Cholesterinized antigen.* Nine remained strongly positive after treatment. The one that became negative was only weakly positive in a congenital case before treatment. *Beef heart antigen.* Seven remained strongly positive. One became moderatively positive from strongly positive. One became negative from weakly positive. One was negative before and after treatment.

Summary. Twenty-four cases. *Cholesterinized antigen.* Nineteen remained unchanged. Four became less positive. One became negative. *Beef heart antigen.* Seven remained unchanged. Seven became less positive. Ten became negative.

The exact status of the cholesterinized antigen in the Wassermann reaction is still a matter of debate but most observers agree that in known syphilities at least, the test is more delicate than the older methods. This series would support that theory. With one exception, (Group 1, case 1), the cholesterinized antigen was equally or more strong than the beef heart antigen tests before and after treatment. According to this test only one out of the ten early cases of Group 1 changed for the better. The milder secondary cases in Group II responded in a more satisfactory manner although the number treated was hardly enough to justify a positive statement. The late cases of Group III, where the spirochetes might be said to be well entrenched, failed to show improvement in again nine out of ten cases. Keeping in mind the fact of the much less senative action of the beef heart antigen the end results of that test show a proportionately unsatisfactory condition of the blood picture. Thus it would

seem that the neosalvarsan has the least effect in those cases where a maximum efficiency is most desired. Viewing the therapeutic action of the concentrated neosalvarsan from the serological standpoint it would seem the part of well thinking conservatism to regard it as a remedy giving excellent temporary aid rather than the more lasting effects of the old salvarsan.

SUMMARY.

I. *Technique.*

1. Intravenous injection of 20 c.c. of fluid with glass syringe, needle and Swift holder most simple method.
2. A steady hand and careful adjustment of syringe to needle necessary.
3. The time of actual injection averaged thirty seconds.

II. *Sequelae.*

1. Three hundred and forty-one injections given.
2. No patient required the use of the recovery rooms because of untoward sequelae.
3. Dizziness, headaches, and diarrhea in mild degree recorded in some instances during the first twenty-four hours especially after the first injection.
4. Experienced operator and strict aseptic technique render danger negligible.

III. *Therapeutic Efficiency.*

1. Twenty-four untreated cases were given four injections of concentrated neosalvarsan, dosage 0.45 gram at weekly intervals followed by a Wassermann seven days later.
2. Active symptoms and lesions yielded readily.
3. The Wassermann reaction was little changed.
4. Active early cases or long standing cases showed the least serological change.
5. Serologically, the concentrated neosalvarsan was inferior to the old salvarsan.

CANCER OF THE TONGUE BASED UPON THE STUDY OF OVER ONE HUNDRED CASES.*

BY JOSEPH C. BLOODGOOD, M.D., BALTIMORE.

This study has led to some very remarkable conclusions.

It has been demonstrated that the failure to cure when the cancer of the tongue is fully developed is due chiefly to the neglect to remove the muscles of the floor of the mouth below the cancer.

* Author's abstract of paper read before the American Surgical Association, New York, April 9, 1914.

The high mortality after operations for cancer of the tongue is chiefly due to the removal of the floor of the mouth without removing a section of the lower jaw.

The investigation has also shown that if a lesion of the tongue is subjected to immediate operation within a few weeks after the onset of the lesion, the chances of a permanent cure are best. In this stage it will usually be sufficient to remove the local lesion with a good margin of healthy tissue, and this removal should be done with the electric cautery. The centre of the lesion should be preserved for microscopic study. When this is done the chances are that the lesion will still be benign. But even though the lesion prove microscopically cancer, the probabilities of a cure are almost 100 per cent.

In the past surgeons have apparently removed too much of the tongue and have performed too extensive operations upon the glands of the neck. Now this is theoretically incorrect, because cancer of the tongue infiltrates into the glands of the neck through the floor of the mouth. Should the glands be involved and the floor of the mouth not be removed, one could hope for little, if anything, from such an operation. If the glands of the neck are not involved, this does not preclude infiltration of the floor of the mouth.

When the operation is performed in one stage it is impossible to remove the tongue, the floor of the mouth, and the glands, and then to close the opening in the mouth, unless a section of the lower jaw is also removed. If the former operation is done thoroughly the mortality is very high—almost 80%—from primary or secondary pneumonia, or a late infection from the oral fistula.

The author was first impressed with these facts when it was found that the first cured cases were either cancer originating in the floor of the mouth, or cancer of the tongue invading the floor of the mouth, in which it was absolutely necessary to resect portions of the lower jaw in order to remove the disease. The extent of the disease, therefore, forced the surgeon to the more radical and mutilating procedure, and allowed him to perform removal *en-bloc*. During the same period earlier and more favorable cases were subjected to less extensive operations. When the floor of the mouth was not removed local recurrence always followed, and when it was thoroughly removed the patients died from the operation.

The author in November, 1910, for the first time deliberately, in a favorable and early cancer of the tongue, removed the right half of the tongue, the right floor of the mouth, the right half of the lower jaw and the glands on the right side of the neck in one piece. The wound was closed by suturing the mucous membrane of the right cheek to the remaining half of the tongue. The patient swallowed at once after the operation, and no recurrence followed. The micro-

scopic study showed that the floor of the mouth was infiltrated but the glands were free.

As the removal of the lower jaw, especially in the region of the symphysis is mutilating, the author has attempted to accomplish the same results in a different way.

The glands of the neck are first removed and, after the operation, their connection with the floor of the mouth below the lesion is thoroughly burned with the cautery, and the wound closed. Then the lesion in the tongue or floor of the mouth is attacked with the electric cautery. The application of this is usually repeated two or more times, until everything is destroyed down to the area of the first cauterization from below. The healed skin flap of the first operation forms the floor of the mouth and prevents an oral fistula.

The first operation after this method was performed in April, 1912,—two years ago. The lesion was a cancer occupying the floor of the mouth between the tongue and the symphysis of the jaw. It was about the size of a silver dollar. Permanent cures have been accomplished in similar cases by an *en-bloc* dissection of tongue, floor of the mouth, jaw and glands. The oldest case lived fifteen years, but this is a very mutilating operation, and the recent patient refused to submit to it. This led the author to attempt what he had had in mind for some years. At the present writing, two years since operation—there is no evidence of recurrence and no mutilation.

Since then four cases have received this treatment with, so far, apparent success.

The majority of cases of cancer of the tongue seek surgical aid at an unnecessarily late period. In every case the patient is warned. There is always something to be seen and felt in the tongue or floor of the mouth. If such a lesion is investigated at once, a local operation with the electric cautery should be sufficient; in a little later stage removal of the glands and repeated cauterizations in the mouth; in still later stages resection of the jaw must be done. The author's recent experience seems to show that this operation should be done in stages. First, thorough removal of the glands with cauterization of the floor of the mouth from the neck wound; second, cauterization of the lesion within the mouth; third, removal of the lower jaw and cauterized area. These points will be discussed in detail with illustrative cases in the complete paper.

When the cases observed until 1908,—a period of 18 years,—are compared with those observed during the past five years, the influence of education is well shown. The very early precancerous lesions have increased from 8 to 30%. The late and inoperable cases have decreased from 18 to 10%. The cures have increased from 21 to 50%.

When the author considers the cases personally operated on by him by these newer methods in the past five years (14 in all) he finds that there has been no postoperative mortality, and so far but one patient is dead of recurrent carcinoma. In this case the lesion of the tongue had previously been subjected to operation, the recurrent tumor was extensive, and the glands of the neck involved.

In this group every type of operation according to the newer methods just described is represented. At the present time there is evidence of recurrence in only one case; here the lesion was most extensive and the operation most radical.

The experience with these 14 cases proves the point as far as the immediate mortality is concerned, because considering all cases studied, the postoperative mortality has been about 22%. Since recurrences as a rule take place within one year of the operation, the results in these 14 cases also demonstrate that the improved methods promise a much larger per cent. of permanent cures, and certainly a longer freedom from recurrence.

We have, therefore, apparently conquered the technic of operations for cancer of the tongue. Now, if we can educate men to come earlier, we shall probably conquer the disease.

THE USE OF IODOFORM OIL IN JOINTS.

By E. G. Brackett, M.D., Boston,

Surgeon to Orthopedic Department, Massachusetts General Hospital.

[From the Orthopedic Department, of the Massachusetts General Hospital.]

The use of medicinal agents in joint cavities is by no means new. That it has not always met with success is also well known, yet the principle is sound, and tallies with other surgical methods of today. Many of the results have been bad, because of some disaster, and others negative as to the final results; either because of some of the difficulties of technic and of the great risks under the older methods of surgery, or because of the improper selection of cases. The report of the results in the series here recorded is in the line of similar procedures, but may differ in some matters of technic and in the selection of cases.

There are two general types of cases for which the procedure may be used:—

1. Those in which there is no active disease at the time, and in which the object of the injection is largely mechanical, as, for instance, cases of old arthritis with adhesions, in which it is necessary to keep the surfaces apart after freeing the adhesions.

2. Those in which there is present active disease, and in which the object of the injection is largely for the effect of the agent employed

on the immediate process, as, for instance, in synovitis, of tubercular, Neisser, or other origin.

In all cases, the two things to be considered are:—

I. The special features of the technic of the operation.

II. The type of case to which the procedure is applicable.

I. *The Technic.* Several points in this procedure demand emphasis.

(*a*) The injection is always made by open incision, and not by puncture.

(*b*) Sufficient fluid is always left in the joint to keep the capsule under tension, therefore some form of stitch is necessary by which the tension can be maintained at the time of the withdrawal of the syringe.

(*c*) The adhesions, in old cases, are broken up before the joint is filled with oil and the capsule closed; other than this no violence is done to the cavity of the joint, and no handling is permitted, particularly of the tubercular joints.

(*d*) Fixation by plaster, or splints, is seldom used.

The Incision. The open incision is always used, and a word is necessary in reference to the choice of this method of inserting the oil, instead of by trocar injection. As a matter of fact the two methods have hardly enough in common to make a comparison. It is often not easy to find the cavity of these joints, not distended with fluid, even by a clear open incision, and, in the acute cases, with the very great edematous swelling of the synovial capsule, it is often difficult to find the cavity of the capsule. The synovial membrane is redundant, the pannus may cover a large part of the articular surfaces, these two surfaces are in contact and roll out into the incision, so as to completely block it, and, in the acute cases, as in the active stages of tuberculosis, the thick, velvety, synovial membrane protrudes into the wound, almost like a hernia. In the older cases with adhesions, the cavity is more or less obliterated, and a trocar will make a small area about its point. In the early cases, with a thick redundant membrane, one has only to experience the difficulty of finding the capsular cavity, even by an open and easy method, in order to realize the difficulty of finding it by a blind trocar puncture. The direct entrance by a clean cut is far more surgical than the blind hunt by a trocar, and likely to do far less damage. Another reason for the open method is the opportunity of obtaining a specimen for examination, to determine the nature of the infection. I believe it justifiable to open in some cases, to insure diagnosis, when the procedure is not dangerous, and may be advantageous. It is only too easy to call a joint case tubercular or otherwise, but in very many cases to which this method is applicable, it is impossible to positively make a diagnosis without further evidence than the clinical signs. The method is practically safe with extraordinary precaution.

The incision in the skin (preferably on the inner side) (Fig. I.) is a blunt ellipse and the flap dissected back the width of the ellipse. An ellipse with the flap in the opposite direction, shorter than the skin incision, is made in the fascia, and also turned back. It is not always possible to successfully complete this flap when the fascia is very thin and adherent. A straight incision, shorter than the fascia flap, is then made in the capsule, about one-half inch from the border of the patella, in the vertical direction of the leg. The patella lies in the middle or slightly below the middle of the incision.

The Stitch. In order that the capsule may be kept under tension while the fluid is left in the joint cavity, it is necessary to have some form of stitch which not only will make an oil-tight cavity, but also will hold the capsule firmly about the nozzle of the syringe while filling the joint, and will immediately close the opening on its withdrawal. It would seem a very simple method to determine on such a stitch, but several methods were tried before it was found that the most effectual was a double mattress, one enclosing the other. (Fig. 2.) The capsule is closed, beginning at the two ends, and carrying the needle through the fibrous portion of the capsule, but not quite through the synovial portion. By so doing, the soft, spongy synovial tissue is pushed up against the stitch by the pressure of the oil, and acts as a kind of valve. The capsule is closed from either end, with the exception of a space of three-eighths to one-half inch in the centre. Two mattress sutures are then placed in the same manner as the first sutures, one with the opening pointing above, and the other below, the second smaller than the first and enclosed by it. The syringe is then inserted between the threads of the inner mattress, and both drawn firmly about the nozzle. (Fig. III.) When the cavity is fully distended the syringe is withdrawn, the inner mattress is first pulled, then the other, and both tied. (Fig. 4.) The double ellipse flaps give two coverings to the capsular incision, and an additional protection against direct entrance to the joint. Silk is used in all of the sutures.

Preparation Used. Olive oil has been used in all of the cases of the series. Glycerine has been used by many operators and has had much favor, but does not seem to be so well adapted to use in these cases, on account of its hygroscopic properties. It is necessary to have a medium which will resist absorption, and remain in situ to protect the surfaces as long as possible. Very great care should be used in the selection of the oil; it must be of pure quality and of neutral reaction. Very many of the olive oils contain acids, which tend to disorganization and the freeing of some irritative products, as well as to the liberation of the iodine. Some of the irritative results, following the use of oil for surgical purposes, as for instance in the abdominal cav-

ity, have probably been due to this cause. The oil in all of these cases has been the French oil of Antoine Chiris. It is sterilized for one-half hour in boiling water, in a cotton plugged bottle, the top being also covered by rubber tissue, which is kept in place until the oil is used. Enough of the solution is used to fill the joint under tension of its capsule. For an adult joint three and one-half to four ounces is a sufficient amount. The special feature which must be borne in mind in all cases is the necessity of keeping the joint cavity sufficiently distended, to prevent the surface of the synovial capsule from coming in contact either with itself, or with the other articular surfaces, therefore it is necessary that the oil be left with the joint capsule under tension. This is Nature's way of protecting an acutely inflamed joint. In the usual synovitis, an excess of fluid is poured into the joint, separating the synovial surfaces, and this acts in two ways: first, to keep the inflamed surfaces from contact, thus diminishing the pain; and, second, to thus prevent adhesions in the acute stage, when adhesions are formed so easily. When the fluid is early absorbed, or removed, and the surfaces allowed to come in contact, while still acutely inflamed, the pain and sensitiveness, and the tendency of adhesions is increased. By imitating Nature's method,—filling the cavity with fluid,—the freshened surfaces are kept from adhering in the cases in which adhesions have been broken up, and, in cases of active disease, a decided amount of rest is given to the inflamed synovia, through the avoidance of friction.

In old cases with adhesions it is necessary to freely break up all bands in order to obtain as large a capsular cavity as possible. Many old bands are so strong as to give risk of fracturing a portion of the articular surfaces, and these may be cut with much greater safety. Also, experience of many operators has shown that the ordinary forcible straightening of these knees, held firmly by strong adhesions, is attended with a large element of danger. Many times the adhesions are stronger than the bone, which is much atrophied by long restricted use, and force results in a tearing off of a fragment of the articular surface. Puncture by trocar, at the best, will find only a small isolated cavity, and cannot meet the conditions which demand thorough freeing. It is particularly essential, in this class of cases, that sufficient oil be left in the joint to insure the actual distention of the whole capsule. Naturally, fixation in plaster is not indicated.

Selection of Cases. This method is applicable to:—

1. Cases of old infectious arthritis, with adhesions and with partial obliteration of the capsular cavity, but with no true ankylosis, and without destruction of cartilage.

2. Cases of infectious arthritis, in the acute stage, particularly those of Neisser origin, and more especially the type where there is one remaining persistent joint, which usually results in ankylosis.

3. Cases of primary synovial tuberculosis before involvement of cartilage or bone.

4. Cases of osteo-arthritis, with marked thickening of capsule and with pannus, in the sensitive stage, but before there has been loss of cartilage.

In other words, the method may be used in the affections of the synovial membrane, either when it is desired to keep the surfaces apart, or when it is desired to apply a remedial agent to the joint surfaces.

For the purpose of illustration, one case (a favorable one) of each of the types to which the method has been found applicable will be cited.

Case 1. An infectious arthritis of two or three years' standing, which had had several times brisément forcé. At the time of operation the case showed increasing sensitiveness, disability and pain; knee held in flexion of 20°; motion 5 to 10°, all painful; knee swelled; capsule evidently very markedly thickened; patella not movable. X-ray showed fragment of bone on the inner side of the joint, apparently from a fracture of a portion of the articular surface of the inner condyle, and a corresponding space on the under and anterior surface of the inner condyle. Incision was made along the inner side, the capsular cavity was found practically obliterated, with only a few small areas or pockets remaining to indicate the capsular cavity. The patella was so strongly adherent that it could not be freed by either blunt dissection or with the finger, but required the knife or scissors. There were no surfaces of bone exposed, but all articular areas were covered by thick, tough membrane, apparently simply inflammatory in character. On the other side, a piece of bone with cartilage upon one surface was found lodged between the tibia and condyle. This was removed, and the areas of cartilage which were exposed by this were clear and white. About one-half of the capsular cavity was restored. The adhesions on the outer side were so firm as to resist all attempts at freeing, except by actual section, and complete restoration of the joint cavity was not attempted. The joint at this time allowed flexion to 80° and nearly complete extension. The joint cavity was then filled with oil with the capsule under tension.

The case showed practically no pain during convalescence, which was uneventful. Knee kept in fixation for about two months, but slight amount of motion was given each day without force. Patient began walking with crutches in a month and during the following months used leg increasingly.

Twelve months later the knee allowed extension to within 5° of normal; 90° flexion; thickening had markedly disappeared; practically no pain; patella was somewhat movable from side to side. Patient walked without protection about the house and with a splint allowing motion on the street. Eighteen months after operation patient walked several miles daily without cane.

Microscopically the specimen showed an old chronic inflammatory process, and although every attempt was made to find evidence of some tubercular process the examination was negative in this respect.

CASE 2. Neisser infection, polyarticular. All joints cleared in the usual time, excepting one knee, which remained persistently painful, swollen and sensitive; flexed at 20°; no motion on account of marked spasm and pain; no fluid; very marked thickening of capsule. Case apparently one of the types in which in one joint the Neisser infection remained, and there being no fluid to keep the surfaces apart, it gave every indication of a stiff joint from adhesions. No progress had been made for two months. The joint was opened by incision on the inner side, a few adhesions found, but these were easily broken up, the joint moved to a position of 90° flexion, and the capsule, filled with oil, was left under tension. Little pain in convalescence. Motion allowed of a few degrees in a week. After three weeks gentle passive motion was given, which did not cause particular pain. Recovery with full extension; flexion to 110°. Patient has been able to work freely since (2½ years).

CASE 3. Tubercular synovitis of six to eight months' duration. Unable to work for six months; knee flexed at 45°; motion practically nil on account of spasm; whole knee swollen; tender; marked capsular thickening; no fluid; complete disability. X-ray showed no involvement of bone; articular surfaces clean; normal cartilage space between bones. T. B. von Pirquet reaction, positive. Incision on inner side opened to markedly thickened synovial membrane, fragile, vascular, of typical tubercular appearance, pannus extending over to the edges of the articular surface of bone; remaining cartilage clear, smooth; no sign of erosion of any part of joint that could be inspected through the incision. No manipulation was given to the inside of the joint except to remove a small bit of the synovial capsule sufficient for microscopic examination. Oil injection, under tension. Recovery from operation negative. Leg in plaster for several days. Split plaster allowing passive motion daily. At end of eight weeks a second injection was given, and at this time free oil was found in the joint. No weight-bearing was allowed for six months, but patient wore a split plaster and used crutches. At end of eight or nine months patient returned to work with plaster. Two years later leg showed practically normal motion except that of extreme flexion; no swelling; no tenderness. Has worked for 2½ years at his occupation as a plasterer with no return of symptoms. Microscopic examination of specimen showed the process to be tubercular.

CASE 4. Infectious arthritis with hypertrophic areas, with increasing disability for two years. Permanent flexion of knee of 15° to 20°; motion allowed in 25°; marked capsular swelling and villous condition, evident to palpation; pain and sensitiveness with use, to such a degree that disability was nearly complete. X-ray showed hypertrophic process, without involvement of cartilage. This case had a somewhat multiple arthritis, but the knee had been the longest involved and its disability was the greatest. The process was not at the time active. Incision on the inner side showed thickening of whole synovial portion of capsule, pale in color, with pannus extending over onto the edges of the articular surfaces but not covering them, and several large lipomata, which were removed. Oil injection under tension. Motion allowed at end of two weeks. No pain during convalescence. Three months later swelling and capsular thickening had disappeared; knee could be extended freely and flexed to 100°; no pain on weight-bearing. Eight months later knee had remained quiet; patient was using joint freely; there was no swelling of capsule; crepitus had disappeared.

The list in this series includes cases of the four classes above mentioned operated on by this method. The post-operative period of observation varies from six months to four years. From the study of these cases the following summary has been made:—

The first group comprises the cases of old infectious arthritis with adhesions—object of operation may be called mechanical, viz., to keep apart the freshened surfaces after freeing the adhesions—10 cases. Seven have been successful. Two were unsuccessful and they showed by x-ray destruction of the articular surfaces. These two illustrate the type of case which should not be attempted by this method, viz., the cases in which the arthritis has resulted in destruction of cartilage. In both, this destruction was present, and the operation gained nothing. In the others, motion resulted varying from 45° to 100°. In cases sufficiently severe to warrant an operation it is doubtful if complete motion is ever to be expected.

The second group comprises the cases in the earlier stages of disease. Object of operation is also in a large measure mechanical. This group includes the three types, viz., (*a*) acute infections (Neisser, etc.), (*b*) early tubercular synovitis, (c) chronic infectious (osteo-arthritis, etc.).

Type A—Neisser and Acute Infectious. Three cases have been treated, none in the very early stage. With the strong tendency of this form to a spontaneous recovery, it is doubtful if this operative procedure is to be generally advocated in the early period of the disease, for it is recognized that this infection is the most amenable to treatment, and in the usual case, even in the persistent joints, radical measures are rarely necessary. But these joints do occasionally go on to destructive changes, and it is in these persistent ones, before this stage of articular invasion has been reached, that the use of oil is to be advocated. It is in this later stage, where the capsular thickening persists, where adhesions are forming and becoming firm, that the indications for this operative treatment are evident, and has resulted in a rapid diminution of the capsular swelling, disappearance of pain and sensitiveness, with increase of motion.

Type B—Tubercular Synovitis. This type forms the most interesting of the group. It can be definitely stated that the operative procedure is not applicable to cases in which there is involvement of the articular surfaces. The old records of cases show that these cases of tubercular disease of the knee practically all came to ankylosis or to excision; but the records also show that the average case did not present itself for treatment until about two years after

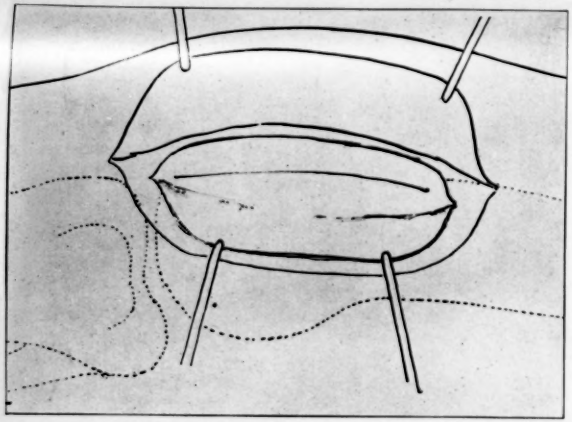

FIG. 1.

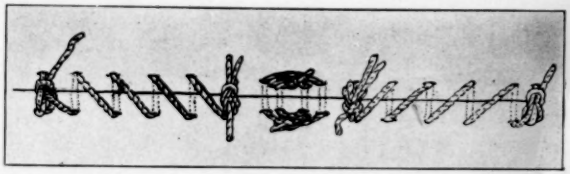

FIG. 2.

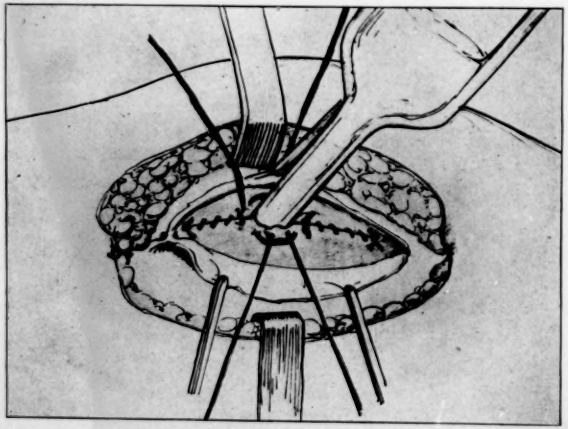

FIG. 3.

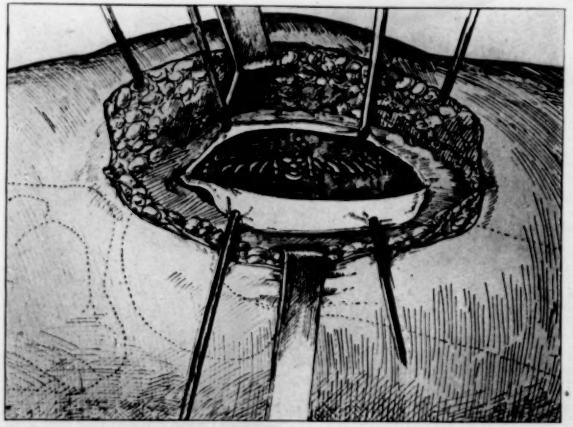

FIG. 4.

the onset of the disease, and at this time the disease was well advanced. At present many cases are seen in which there is no evidence, either clinical or by the x-ray, to indicate involvement of bone, either because diagnosis of these conditions is made in much earlier stages, or because the cases are presenting themselves earlier in the course of the disease. Moreover, the further study of these cases, especially by early operation, shows that a large number of these begin as a primary tuberculosis of the synovial capsule. The excision of these knees, in this stage of purely synovial disease, is a step most radical, yet experience has shown that these cases progress more or less steadily to distinct bone disease. It is in this stage that the attempt has been made to cut short the process by the internal medication of the joint. The usual ultimate result is such an unfortunate one, that attempts to this end are to be desired, provided the method is a safe surgical procedure, and a few favorable early cases gave encouragement. Ely has shown that the cure of the tuberculosis is in many instances by the formation of fibrous tissue, and may serve as the means through which the cure is effected in these cases, but so far there is no proof in this series. One feature of this method, by no means an unimportant one, is the establishment of a positive early diagnosis, a thing not always easy or even possible by clinical signs alone, in the early stages of the process, and the evidence thus obtained in these cases has very materially aided in the general diagnosis of the early tubercular joint lesions.

Thirty cases are available for report. From the standpoint of the results they may be divided into three groups.

1. Cured Cases (8). It is doubtful if the final result of a disease so insidious can be definitely given until a very long time has elapsed. Freedom from symptoms, even for a year, is not sufficient to warrant placing the case among those cured, as has been shown by one of the best early results. An apparent cure has occurred in eight cases, which have stood the test for one and one-half and two and one-half years. The cases were placed as cured by the following tests: Freedom from pain or sensitiveness, maintenance of motion, absence of added deformity, absence of capsular thickening,—all with continuous use.

2. Arrested Cases (14). To this second group belong the less successful and more usual cases, which have not shown definite improvement. There has, however, been a decided checking, as shown by the diminution of (1) sensitiveness, (2) deformity, (3) swelling of the capsule, by the maintenance or increase of motion. In these cases, the x-rays have given no evidence of extension of the disease to the erosion of cartilage or involvement of bone. In other words, the condition has changed from one in which the evidence was pointing toward a progressive process, to a condition in which the evidence was directed toward a retrogressive process of the disease. The question will arise whether this was not the result of the usual rest and fixation of the treatment, but the fixation was no greater than before, and usually much less, for these joints are not kept in perfect fixation, and the change in the clinical course was too synchronous with the operation to be regarded as a coincidence.

3. The unsuccessful cases (8) are those in which there has been no decided improvement, or the present state cannot be learned. Three were Italians who have quite dropped out of sight. Experience has shown that these are not a favorable class. A few were operated upon in which the x-ray showed a slight involvement of the articular surfaces and the result in these was uniformly bad. The disease was in no way checked, and the cases came later to an excision.

At the present, the most practical value of this operative procedure, in these tubercular cases, depends upon the value which is put on the "checking of the disease." To estimate this, one must have in mind for comparison, the usual course of this disease under fixation and rest. Without exception, the non-operated cases which have been kept under observation, have progressed steadily, by a remitting course, to increasing disease and to increasing disability, and ultimately to excision or to amputation. This applies also to the old cases in the past, whose records have been looked up. Besides the three cured, in seven of these cases there has been decidedly an arrest in the condition as shown by the symptoms, the clinical signs, the x-rays, and the clinical usefulness of the joint. This seems decidedly a gain, particularly when it is considered that this is the stage when excision would not be resorted to, at least as a routine. It must be also borne in mind that the after-care in an out-patient clinic cannot be properly carried out, and many times patients were found walking on the joint three or four months after operation, when fixation had been carried out up to the time of operation.

Type C. Chronic Arthritides. The cases of chronic arthritides in which benefit has been obtained are those of the osteoarthritic type, of the chronic form of the infections, with enlarged villi but without the destruction of cartilage. The procedure is not of use in the atrophic type, or in the atrophic stage of the infectious type. Three cases of this type have been operated upon and without benefit. The cases which have been benefited have shown a decided diminution of the capsular swelling and thickening, diminished sensitiveness and increased use of the joint, and of this type three cases have been operated upon with distinct benefit to each.

CONCLUSIONS.

This method is applicable to the cases of capsular involvement, of various types of infection, and in the stages in which there is no involve-

ment of the articular surfaces. These cases may be divided into two groups:—

1. Cases of old infection in which adhesions have been freed, and it is desirable to keep the surfaces apart. (The use in these cases is largely mechanical.)

2. Cases of infection, of

(*a*) Acute infection (Neisser, etc.).

(*b*) Tubercular synovitis (early stage).

(*c*) Chronic arthritis (selected cases).

The procedure is in no way a substitute for arthroplasty; is not applicable to cases of disease of any origin, in which the x-ray shows involvement of the articular surfaces; but is essentially for those cases, only, in which the abnormal condition is confined to the synovial membrane. In tubercular cases, the early cases naturally show the most marked definite improvement, and in these cases repeated injections are advocated, preferably at intervals of eight to twelve weeks. This procedure should be considered as an incident in the treatment of the tubercular synovitis, not a substitute for the fixation and rest. Neither is permanent fixation desirable. The absolute immobilization is, perhaps, quite as disastrous as the other extreme. A daily gentle passive motion, without forcing the arc of motion allowed, is decidedly a benefit, does not increase the activity of the disease, and does prevent the contraction of the capsule and formation of adhesions.

In Group I, in which the object is largely mechanical, the motion is begun early, within the first two or three days, but never with violence or even to the point of causing pain. In the other cases (*a*) and (*c*) of Type A, the acute infectious and the chronic arthritides, motion is also begun early, on the third or fourth day, and given once or twice daily. After two weeks the leg is put in a split plaster, and locomotion allowed without weight-bearing.

Medical Progress.

REPORT OF PROGRESS IN SURGERY.

BY JOHN BAPST BLAKE, M.D., BOSTON.

IT becomes yearly more and more impossible to give, within moderate limits, an adequate outline of the progress of general surgery as indicated by current literature. The number of monographs steadily increases, and the duty of the reviewer becomes correspondingly complicated, even with the assistance given by abstracts and indexes. America is certainly contributing, at present, a generous share to the sum-total of investigation and treatment of disease. This is true both in the output of the laboratories and of the surgical wards of the hospital.

In a way, it may be said that conspicuous advances have been made in the broad sub-division of,—anesthesia; surgery of the head; standardizing treatment of fractures; surgical conditions of the thorax; surgery of the stomach; sterilizing the skin both in minor injuries and in preparing for operations.

1. Anesthesia:

There have been at least one hundred important monographs on this subject in the past twelve months. These papers have ranged from the Anoci-association of Crile, through local anesthesia pure and simple, to the new rectal anesthesia of Gwathmey.

RECTAL ANESTHESIA.

Technic for the introduction of oil ether—colonic anesthesia devised by J. T. Gwathmey, M.D., abstracted by Charles Gordon Heyd, M.D.

Contraindications: 1. Whenever ether is contraindicated *except* when the patient has been ill from a previous administration. Here it can be given with impunity. It can also be given in bronchitis, asthma. 2. Pathological conditions of the lower bowel, colitis, hemorrhoids, fistula, etc. 3. When the patient complains very much upon its introduction.

Preparation of the Patient: 1. A laxative, mild, avoid all purging. 2. Irrigation of the colon until the return is clear, three to four hours before operation.

Apparatus: 1. A small catheter and a funnel. 2. Two small rectal tubes inserted side by side to flush and withdraw fluid.

Administration: 1. *a.* One hour before operation: Morphine, 1/8 to 1/4; atropin, 1/200 to 1/100 by hypo.; *b.* one-half hour before operation per rectum: Chlorotone, gr. 5-10; ether, drams 2-4; olive oil, drams 2-4; 2. *a.* Mixture for adults: Olive oil, oz. 2; ether, oz. 6. Mixture for weak anemic patients: Ether, 55, 65%; oil, 45, 35%. Mixture for children: Ether oil, 50%. *b.* Patient in Sims' position. The catheter is well lubricated and inserted, four inches within the rectum. The mixture poured slowly into the funnel, at least 5 minutes being consumed. Introduce oz. one, for every *twenty* pounds of body weight except for obese. From 10 to 30 minutes is necessary before patient can be moved.

Danger Signals: 1. Loss of lid reflex. 2. Stertor or embarrassed respiration. 3. Approaching cyanosis. If any of the above signs are present withdraw two or three ozs. of the mixture from the rectum immediately. If the breathing is regular with reflexes active, the patient will be relaxed and in surgical narcosis.

Post-Operative: Immediate irrigation of the colon with cold-water soap suds. Then withdraw one of the tubes from rectum and introduce two to four ozs. of olive oil and one pint to one quart of cold water. Withdraw tube from the rectum.

It is interesting to recall that more than 20 years ago Post made observations upon rectal anesthesia here in Boston, and at a much more recent period Cunningham and others did similar and more extensive work. A rather large number of deaths were, however, reported from various parts of the country following rectal anesthesia and the method has been recently much less in evidence. With the new technic of Gwathmey, rectal anesthesia bids fair to become a valuable addition to our methods of producing general narcosis.

LOCAL ANESTHESIA.

The field of local anesthesia is spreading rapidly, not only in the variety of surgical procedures for which it is applied, but also in the steadily increasing number of surgeons who are perfecting its technic. It must be emphasized that local anesthesia requires a very careful, painstaking, and somewhat tedious technic if it is to produce its maximum effect. Altogether too often has the surgeon blamed the anesthetic in the past, when his own inaccurate methods were the cause of failure.

Two drugs have rapidly taken the place of all others in the local field:

1. Novocain.
2. Hydrochlorid of quinine and urea.

These two make the use of cocaine for the general surgeon entirely unnecessary, since they are equally efficient and far less toxic.

In an admirable paper on local anesthesia in *Surgery, Gynecology and Obstetrics*, 1913, p. 842, Dr. J. F. Mitchell presents the developments and modifications that have occurred in the previous five or six years.

This monograph covers the field so completely as to make it unnecessary to quote others at length.

Rood: *British Medical Journal*, 1912, No. 2, p. 1701, describes in considerable detail what he calls regional anesthesia, that is to say nerve blocking, at points distant from site of operation, summarizing its advantages in the extent of area anesthetized by a single injection, and, that the site of operation is not obscured by the edema of the injected fluid, and finally that operation may thus be done on inflamed parts, since injection is made a considerable distance away. Anesthesia, he says, last several hours. He reports two hundred and fifty-four cases as very satisfactory, requiring general anesthesia as an addition in only seven.

Braun, in the *Deutsche Medizin. Wchnschr.*, 1913, No. 39, p. 17, discusses the advantage of local anesthesia in the reduction of fractures and dislocations, and reports fifty cases during the previous year, claiming that reduction was easier under local than under general anesthesia. He says that as early as 1885, Conway, an American surgeon, used this method, followed shortly by Von Reclus.

SPINAL ANESTHESIA.

It is a little difficult to say whether on the whole spinal anesthesia is used at present more than it was a year ago; probably it is.

Donaldson, H. J., *American Journal of Surgery*, 1913, No. 27, p. 325, reports two hundred and four cases of spinal anesthesia, consisting of operations on the pelvis and abdomen as high as the gall-bladder; in only fifteen of these either a second injection was required, or a little ether was applied. Thirty-four cases suffered from nausea and vomiting. There seems to have been no other complications. The author thinks it is safer than ether. He does not understand the existing prejudice against its use. He uses stovaine for anesthesia.

Babcock, *Journal Am. Med. Asso.*, 1913, p. 1358, contains an excellent article on spinal anesthesia in gynecology and obstetrics and abdominal surgery. He says that since 1904 five thousand operations have been performed under spinal anesthesia in the Samaritan Hospital, Philadelphia. Of these, about three thousand were his personal cases. He says that with a similar technic, with the position of the operator and the patient reversed, he himself would have accepted spinal anesthesia. Stovaine has been chiefly employed. The repeated production of spinal anesthesia in the same person is no more harmful than a single injection. It may have a large mortality in the hands of one not possessing sufficient clinical skill. He concludes that while not a universal anesthetic, it produces the greatest degree of muscle relaxation with the least protoplasmic disturbance. It is probably more dangerous than a light narcoses under ether or nitrous oxid-oxygen, but it is safer than prolonged narcosis. It causes an earlier and more marked fall in blood-pressure than other anesthetics. It should be avoided in conditions of marked hypotension of the circulation. Headache and palsy mean that faulty solutions have been injected. It is useful in obstetrics, in pulmonary tuberculosis, and heart disease, also in acute peritoneal sepsis. "Against spastic or paralytic ileus it is a most potent agent, and its use will often render operative intervention needless. It is relatively safer in the young and robust than in the enfeebled and toxic."

Bainbridge, *Med. Press and Circ.*, 1913, p. 334, reports personal experience with ten hundred and sixty-five cases, half of which were done under cocaine and the other half under stovaine, or tropacocaine. In all his cases, there was only one death and that was probably from status lymphaticus. The indications for spinal analgesia are the contra-indications for inhalation anesthesia. Some of its objections are that a dose once given cannot be diminished, and that its effect may pass before operation is completed.

Jonnesco: *Zentralbl. f. Chir.*, 1913, p. 469, believes that stovaine and nitrate of strychnine may be injected at any point in the spinal canal without danger. In nearly two thousand opera-

tions he had only two deaths. For anesthesia of the head and upper extremities he makes the injection between the first and second dorsal vertebrae, otherwise between twelfth dorsal and first lumbar vertebrae. Jonnesco is one of the few who recommend spinal anesthesia for operations above the diaphragm; his contentions are not widely accepted.

Nicolich, in a paper read before the French Clinic of Urology, October, 1912, considers spinal anesthesia decidedly superior to chloroform in genito-urinary surgery, because he thinks it is less dangerous and because it makes the operative attack much easier.

ANOCI-ASSOCIATION.

Crile's method has been adopted by many good surgeons, but by no means all. In slight detail, Dr. Crile has modified his technic and now injects the quinine and urea at a distance from the line of incision so that anesthetic effects will cover the whole field of operation, the distance injection doing away with edema of the wound itself which might possibly interfere with prompt healing. Quinine and urea are not used where infection is present. The strength varies from one-half to one-sixth of one per cent.; novocain one-fourth per cent solution. Morphine and scopolamine are used as preliminary narcotics. This technic adds a little to the time of operations. It is fair to say that those who use this technic are convinced that it is followed by a convalescence almost entirely free from pain and from the discomforts which formerly attended major surgery.

It is difficult and unsatisfactory to endeavor to summarize important papers describing new methods. It is only right that the author of these methods should insert original monographs. Either one of two papers by Crile should be consulted by those who desire to follow his precise technic in his method of producing shockless operations; and conclusions should be based, of course, only upon a series of cases in which Crile's precise technic has been faithfully followed. These two papers are "Kinetic Theory of Shock," *The Lancet*, July 5, 1913, and in somewhat more concise and shorter paper "Anoci-Association." *New York Medical Journal*, January 10, 1914. In this latter paper Dr. Crile says, "Comparing the last one thousand operations performed by myself and staff at the Lakeside Hospital, we adopted the fully developed anoci technic with the last one thousand operations; we find that in the former the mortality rate was 4.6 per cent., while in the last one thousand anoci operations the mortality rate was .8 per cent." These figures need no comment.

GAS OXYGEN.

Gas oxygen is unquestionably the safest general anesthetic we possess, but it must always be in the hands of an expert. Crile himself, who has done so much to increase the use of nitrous oxid says in *Clinics of J. B. Murphy*, February, 1914, "Nitrous oxid skilfully given, in my estimation, is the best anesthetic for surgical purposes, but it ought never to be given except by some one who has been well trained in its administration. In my judgment, the degree of M.D. does not qualify a man to give nitrous oxid anesthesia or any anesthetic, in fact. It gives any one a legal qualification, but it does not give one a moral qualification. It takes a special training to give nitrous oxid, for it is the most difficult of all anesthetics to give well. I am speaking about this because I have known of certain fatalities from nitrous oxid anesthesia administered by inexperienced anesthetists. I believe that when well given, it is the safest anesthesia one can use, and I think that nitrous oxid not well given is, perhaps, the most dangerous anesthetic there is. In my own clinic in the Lakeside Hospital we have given nitrous oxid for general surgical purposes eight thousand times."

Nitrous oxide may be given by intratracheal method as described by Boothby and Cotton in *Surg., Gyn. and Obstet.*, November, 1911, p. 572, or more commonly through an inhaler of a perfected apparatus: Cotton and Boothby, *Surg., Gyn. and Obstet.*, September, 1912, p. 281:

I. To be safe, effective and suitable for major surgical work a nitrous oxid-oxygen anesthesia must be so conducted that the patient is never in the least degree cyanotic; on the contrary the patient must always be pink.

II. No attempt should be made to use the dangerous procedure of increasing intrathoracic tension of the gases for the purpose of deepening the anesthesia.

III. In those cases that cannot be sufficiently relaxed for the purpose in hand by the use of nitrous oxide with a sufficient proportion of oxygen to prevent cyanosis, the anesthesia should be deepened by the addition of as much ether vapor as may be needed; experience has shown that the total amount of ether used is small and has little and often no effect on the quick and agreeable recovery incident to this form of anesthesia with its absence of post-operative "surgical shock."

IV. We believe an anesthesia without cyanosis to be safe in expert hands. The anesthetist, however, must have skill and experience to recognize the warning signs of too much nitrous oxide even without cyanosis (a picture not striking enough to appear to the tyrol) as well as the signs of too much ether.

V. Therefore, to be practical for surgical work an apparatus for the administration of nitrous oxide-oxygen-ether anesthesia must possess the following fundamental features:

1. The apparatus must deliver, for any length of time, any desired proportion of nitrous oxide and oxygen, without requiring constant attention from the administrator; in other words the high pressure of the supply tanks must be

automatically reduced to an easily controllable working pressure; the importance of this feature necessitates that the reducing valves be an integral part of the apparatus.

2. It must be possible to add ether vapor in any strength from the merest trace to a high precentage: and any desired variation in this percentage must be gradually and yet rapidly made.

3. There must be a method of instantly estimating by the eye the approximate proportion of each gas being administered.

4. The face piece must be not only air-tight but practically self-retaining.

5. The apparatus must be strong, light and reasonably portable.

VI. The apparatus herewith described and illustrated is designed to meet the clinical and the physiological requirements of surgical anesthesia and it effectively overcomes the mechanical difficulties attendant to the successful administration of nitrous oxide-oxygen-ether.

Other papers on nitrous oxide anesthesia will be found in the *Proceedings of the Society of Biology*, 1912, p. 652, by Ambard and DeMartel, and Collier, *Jour. Med. Asso.*, Ga., December, 1912, who has used it in one hundred and ninety-four cases.

EXTRADURAL OR SACRAL ANESTHESIA.

Lawen, was one of the first to recommend this method and gives a report of his recent experience. He also gives a compilation of the literature in *Ergebn. d. Chir. u. Orth.*, 1913, V. 39. He traces the origin of the method and describes the anatomy of the epidural space and gives technic. He reports sixty-five cases. In three cases anesthesia failed and narcosis had to be added four times. Those who should be excluded from this are the fat, senile, the arteriosclerotic, and those suffering from heart disdisorders of the nerves.

Schlimpert: *Surg., Gynec. and Obstet.*, 1913, p. 488, describes in detail the technic as used at the Freiburg Woman's Clinic where the method is used for both low and high extradural anesthesia, that is to say, below and above the symphysis. The results are as follows:

Low anesthesia; duration from three-fourths to one and one-fourth hours; of one hundred and fourteen cases about half showed complete anesthesia, while one-tenth were failures.

High anesthesia; in three hundred and forty-two cases of high anesthesia forty-six per cent. were complete, and the failures were apparently a little more than in the low cases, though the figures seem to be contradictory.

INTRATRACHEAL ANESTHESIA.

Intratracheal anesthesia will presumably continue indefinitely to be practiced only by exease, nephritis, anemia, or functional or organic perts. Its dangers in the hands of the unskilled are acknowledged. Its advantages, particularly in surgery of the brain and face and thorax, are indispensable. Gas oxygen instead of ether may be used as an anesthetic.

Boothby-Cotton, have written an excellent paper, perhaps as good as any which has appeared, bearing upon both physiological and clinical aspects, "Intracheal Insufflation," *Annals of Surgery*, January, 1913. A list of ninety references covering all the most important articles bearing upon the subject is appended. Its conclusions are as follows.

1. Intratracheal insufflation respiration is the only artificial method that absolutely provides for a sufficient aeration of the lungs, regardless of the respiratory movements of the patient, and that properly administered and safeguarded can be rendered devoid of intrinsic danger.

2. In consequence, anesthesia by this method is indicated whenever the operation is about to interfere in any way with the ability of the patient to voluntarily respire.

3. Therefore it ought to be used in all intrathoracic work and in extensive operations about the head, neck, mouth.

4. Of the various anesthetics to be used with this method, ether with air, preferably supplied by a foot pump, is the most applicable for general use; however nitrous oxide-oxygen with minimal quantities of ether may occasionally be the anesthetic of choice.

5. To prevent deaths from emphysema, no matter what form of apparatus is used the same must be provided with a *safety-valve* by means of which the intrathoracic pressure cannot exceed 15 mm. mercury.

The technic of inserting insufflation tubes is given by Jackson himself, *Surg., Gynec. and Obstet.*, 1913, p. 507. It must be done under full anesthesia, the patient's head fully extended and without gag.

Peck, *Jour. Am. Med. Asso.*, 1913, p. 839, gives his personal experience with intratracheal insufflation anesthesia in a series of four hundred and twelve cases. He summarizes its advantages as being ideal in intrathoracic operations, lessening the shock, first, through relief of strain on the respiratory apparatus and circulatory and nervous systems, and through the even degree of the anesthesia maintained. It prevents aspiration pneumonia and makes preliminary tracheotomy unnecessary in operations on the tongue, jaws, mouth, nose, and pharynx. It is especially useful in operations about the head and neck and in awkward operations in general. The degree of anesthesia is under perfect control.

Janeway, *Laryngoscope*, 1913, p. 1082, describes a new instrument for catheterizing the trachea, pointing out the advantages of the new method in comparison to the old methods and its convenience to the operator.

INTRAVENOUS ANESTHESIA.

This form of anesthesia is used to a certain extent in some of the foreign clinics, though it has not apparently been widely adopted throughout the United States.

Graef: "Methods of Using Intravenous Ether and Isopral Anesthesia," *Beitr. z. klin. Chir.*, 1913, p. 173, reports five hundred and ten intravenous cases in the City Hospital at Nürnberg without a single death. Contra-indications are the following: myocarditis, marked arteriosclerosis, nephritis, etc. The after-effects are so slight that the patient prefers intravenous to general anesthesia. Strict asepsis and slow injection are absolutely essential.

Honan and Hassler: "Experience with Intravenous Anesthesia," *Surg., Gynec. and Obst.*, 1913, p. 206, report fifty-one cases in which hedonal, ether, and a mixture of paraldehyde have been used. By this method, anesthesia is rapidly induced, the breathing is natural, color remains good, and muscular relaxation is absolutely satisfactory to the operator. The awakening of the patient is prompt and with clear mentality; there is absolute absence of nausea and vomiting. Cases have been those of general hospital service. There was one failure in the early cases. They particularly urge that strict attention be paid to details of technic to insure satisfactory results. The description of the technic in their paper is excellent and complete.

Kepler and Breslauer: "Intravenous Narcosis," *Deutsch. Ztsch. f. Chir.*, 1913, p. 265, carry out investigations in search of an ideal intravenous injection which they think should consist of but a single injection of a small amount of narcotic that would act on brain cortex and have no effect on any other organ. It should be free from danger and its action should pass rapidly after the operation. It is unnecessary to say that their search has not been successful.

Buxton: *Tr. Internat. Cong. Med.*, Lon., 1913, August, publishes a very interesting article on the dosimetric method of administering chloroform based on the fact that percentages of vapor below *one* per cent. do not produce anesthesia but interfere with the temperature and metabolism. Higher percentages induce anesthesia, lower blood pressure, and interfere with respiration. More than two per cent. will impair circulation, and double this amount may be considered fatal. Buxton does not consider any of the mechanical inhalers perfect. He has used chiefly the Vernon-Harcourt regulator and finds it satisfactory. No matter what changes may occur in the patient's breathing, a safe strength, two per cent., should not be exceeded, and even struggling does not call for a restriction of the supply.

Kasashima: "Pantopon-Scopolamine Narcosis," *Beitr. z. Geburtsh. u. Gynäk.*, 1913, p. 90, reports on two series of gynecological operations —in one morphine-scopolamine, in the other pantopon-scopolamine were used. In all cases lumbar anesthesia was used in combination with the narcosis. The author says that pantopon series was more satisfactory. There was less vomiting and less bronchitis. There were no deaths and the one case of collapse was probably on account of the pantopon, as the dose was .02 pantopon and .0003 scopolamine given twice at hour intervals before the operation. Pantopon is an opium derivitive, approximately the equivalent of morphine, but theoretically free from its after-effects.

Diwawin, *Zentralbl. f. Chir.*, 1912, p. 1729, discusses pantopon injections in combination with local anesthesia. His technic is the same as in preceding paper. He reports seventy-two cases, including mastoid, gastroenterostomy, appendectomies, and herniotomies. The patient sleeps, as a rule, for two or three hours after the operation, and has no post-operative pain and no vomiting. Alcoholics are not good subjects. Grave diseases of the heart and lungs, as well as advanced age, may be considered contra-indications for the use of pantopon-scopolamine.

Book Reviews.

The International Medical Annual. A Year Book of Treatment and Practitioners' Index. New York: E. B. Treat and Company. 1914.

This thirty-second annual issue of this standard year-book, edited from Bristol, England, successfully continues the aim of its predecessors to present accurately the progress of the preceding year in all branches of medical science. The progress of the past year was so great and varied that the volume has been increased by nearly 100 pages. It is the work of 37 distinguished contributors, among the new names appearing this year being Dr. Lawrason Brown and Dr. Edward N. Packard, Jr., of New York, and Dr. Beverley R. Tucker, of Richmond, Va. The volume is fully illustrated with 63 full-page plates and 82 cuts in the text. The first part is a dictionary of materia medica and therapeutics, including particularly a general review of radio-activity and electrotherapeutics, a chapter on thorium, and one on tuberculin therapy. The second part is a dictionary of treatment, with special articles on anesthetics, brain surgery, cancer, fractures, hernia, infant feeding, pellagra, surgery of the spinal cord, syphilis, tuberculosis, and typhoid fever The third part is devoted to miscellaneous topics of public health, including medico-legal, forensic, and state medicine. Twenty-eight new terms have been added to the initial glossary.

Though it aims to be cosmopolitan, the English point of view of this publication almost in-

evitably prevents it from noting some important foreign advances, notably so valuable a contribution to the technic of transfusion as the Kimpton-Brown tube. In the main, however, the book covers its field thoroughly and remains a reliable manual of progress for general practitioners.

Diseases of the Heart and Aorta, and Their Treatment. By DR. ARTHUR LECLERCQ. Paris: Octave Doin and Son. 1914.

This volume by the author of "Diseases of the Sixth Decade" (reviewed in the issue of the JOURNAL for Aug. 24, 1911, Vol. clxv, p. 298) may well be classed with that work, indeed it essentially represents a new edition of the volume in that series devoted to diseases of the heart. The first part is devoted to an anatomophysiologic study of the normal and of the abnormal heart, and the methods by which it may be examined. The second part deals with cardiac diseases under the headings of cardiosclerosis, the cardiarteritides, and cardiatheroma. The third part considers the treatment of cardiac and aortic diseases. The book is illustrated with 38 figures in the text and a plan of the heart. Like its predecessors, it is a model of Gallic lucidity, but seems hardly likely to appeal to the busy American general practitioner.

The Treatment of Acute Stenoses of the Larynx. By DR. WILLIAM ZORRAQUIN, Buenos Aires. Paris: Vigot Brothers. 1914.

This monograph deals with the treatment of severe acute stenoses of the larynx requiring immediate surgical intervention. In the first chapter the author discusses intubation and tracheotomy, which he regards as serious procedures and believes often unnecessary. In the second chapter he discusses what he terms the pathologic physiology of these stenoses, and describes the new procedure,—tracheotomy with a tracheal valve,—by which he believes to have obviated the disadvantages of classic tracheotomy, reporting one case in which this method was employed. Even if not convincing, his exposition is of notable interest, and the figures of his apparatus suggestive of possible improvement in the mechanism of tracheotomy.

Outlines of Greek and Roman Medicine. By JAMES SANDS ELLIOTT, M.D., Ch. B. (Edin.). Illustrated. New York: William Wood and Company. 1914.

This admirably written and instructive monograph describes the history of medicine from the half-mythical days of Aesculapius till the death of Paulus Aegineta, when, with the end of the seventh Christian century, medicine, like the other sciences and arts, was plunged into medieval darkness and temporary abeyance. An immense amount of interesting material is here gathered within the limits of very brief space. The text is illustrated with five full-page plates and one line-cut. It is sincerely to be hoped, as the author hints, that the appearance of such a work may be evidence of a recrudescence among physicians of intelligent interest in the history of their own craft, and may stimuate the study of that history, not only by individuals, but in medical schools as part of the professional culture which they impart.

Studies from the Rockefeller Institute for Medical Research. Volume xviii. New York: The Rockefeller Institute for Medical Research.

This volume of reprints represents the results of investigations conducted at, or under the auspices of, the Rockefeller Institute, during 1913 and a part of 1912. It consists of 60 papers, in English or German, by a number of different workers, in various departments of medical science. Most noteworthy among them is Flexner's Huxley lecture on "Problems in Infection and Its Control," and the continuing papers of his series on poliomyelitis and meningitis; the work of Rous and others on chicken tumors; of Noguchi on syphilis and the spirochetes; of Loeb on parthenogenesis; and of Peabody on the inorganic metabolism in pneumonia. Many of the papers are abundantly illustrated, and the volume, like others of the series, constitutes a valuable library of recent progress in experimental medical research.

The Pathogenesis of Salvarsan Fatalities. By DR. WILHELM WECHSELMANN, Berlin. Authorized Translation by CLARENCE MARTIN, M.D., St Louis, Mo. St. Louis: The Fleming-Smith Company. 1914.

In his large experience as director of the dermatologic department of the Rudolph Virchow Hospital, Wechselmann has had only a single fatality from the administration of salvarsan. This he reports in detail and from the literature collects three other fatal cases following intravenous injection, six after subcutaneous and fifteen after intramuscular injection, 25 after intravenous injection where death was due to errors of technic, 14 after combined treatment, 25 in which nephritis was the chief cause of death, 37 in which it was acute yellow atrophy of the liver, 10 in which the causes were general, and 39 of miscellaneous character. He also reports some animal experiments, and concludes that in the few fatalities where all other causes can be ruled out, death is due to acute renal insufficiency, not to cerebral hypersensitiveness. He

therefore urges exact technic, judicious dosage, careful study of the urine, avoidance of combined treatment, and special observation of temperature in every case.

The Hypodermic Syringe. By GEORGE L. SERVOSS, M.D. Newark, N. J.: Physicians Drug News Company. 1914.

This book, according to the author's preface, aims to replace Bartholow's "Hypodermic Medication," now out of print. It describes, in a series of seventeen chapters, the varieties of the hypodermic syringe, the technic and indications of its use and the various substances that may be administered by its means. The latter include not only drugs and chemicals, but antitoxins, sera, and bacterial vaccines. The subject of local and spinal anesthesia is also included. The hypodermic syringe is perhaps the most useful instrument in medicine today and seems likely to become even more prominent an agent of progress in the medicine of the future. This volume is a convenient guide in the useful administration of hypodermic therapy.

A Handbook for the Post-Mortem Room. By ALEXANDER G. GIBSON, D.M. (*Oxon.*), F.R.C.P. (Lond.). London: Henry Frowde and Hodder and Stoughton. 1914.

This small volume in the series of Oxford Medical Publications is an excellent concise English manual for the performance of autopsies. The technic described for the removal of organs is a modification of the classic Virchowian method, not the method of removal *en bloc* often seen in this country. The book is illustrated by 13 small cuts in the text. It should prove a useful guide for students and pathologists.

Treatment of Chronic Leg Ulcers. By EDWARD ADAMS, M.D. New York: The International Journal of Surgery Company. 1914.

This monograph, as its sub-title indicates, aims to be "a practical guide to the symptomatology, diagnosis, and treatment" of chronic ulcers of the legs. The different types of ulcer are briefly described and the appropriate treatment of each is outlined. There is also a section on the surgical treatment of varicose veins. The book should prove a useful manual of reference for practitioners.

Sciatica. A Fresh Study. By WILLIAM BRUCE, M.A., LL.D., M.D. (Aber.). New York: William Wood and Company. 1913.

This monograph by Dr. Bruce of Dingwall, N. B., is an exposition of his theory of the pathology of sciatica, which he regards not as a neuritis, but as an inflammatory affection of the hip-joint. After a brief historic survey of the views of Gowers, Lawson and others, he explains his own opinion, and the evidence which has led him to it. The treatment, based on his theory, is rest, fixation, diet, baths, and radiotherapy. A first appendix, illustrated with three full-page plates, presents the anatomy of the sacral plexus and its relation to the hip-joint. A second appendix, constituting half the book, and illustrated with fifteen full-page plates, consists of a brief record of 691 cases of sciatica observed by the author at Strathpeffer from May, 1889, to October, 1912. There is also a bibliography of 23 titles. Whatever proves to be the true ultimate pathogenesis of sciatica, this fresh study of it is a valuable contribution to the literature.

Lectures on Dietetics. By MAX EINHORN, professor of Medicine at the New York Postgraduate Medical School. New York: Paul B. Hoeber. 1914.

This volume consists of the stenographic record of the author's 8 lectures on diet, and essentially covers the field of his previous monograph on "Diet and Nutrition," but with greater variety and more practicality. There are two full-page illustrations and one cut in the text. The book should prove a serviceable manual for practitioners.

Radium Therapeutics. By N. S. FINZI, M.B. (Lond.), M.R.C.S., L.R.C.P., L.S.A. London: Henry Frowde and Hodder and Stoughton. 1913.

The small manual on radium by Dawson Turner, which was reviewed in the issue of the JOURNAL for May 18, 1911 (Vol. clxiv, p. 723), was the first reliable publication of its kind in English. It was concerned chiefly with the physics, and only secondarily with the therapeutics of radium. After a period of three years, during which radium has had an extensive experimental application in treatment, this monograph by Finzi, in the series of Oxford Medical Publications, appears as a legitimate supplement and continuation of Turner's work. After a brief introductory chapter, descriptive of the properties of radium, it is devoted almost wholly to a consideration of its methods of administration, action, dosage, indications, and uses in a variety of affections. An appendix contains descriptions of uranium, thorium, mesothorium, and other radio-active substances. The book is illustrated by 25 figures in the text. It is conservatively written and in the present popular over-enthusiasm about radium is a wholesome guide for the profession as to what may really be expected from this new therapeutic agent.

The Johns Hopkins Hospital Reports. Monographs. New series.

No. I. Free Thrombi and Ball-Thrombi in the Heart. By J. H. Hewitt, M.D.

No. II. Benzol as a Leucotoxin. By Lawrence Selling, M.D.

No. III. Primary Carcinoma of the Liver. By M. C. Winternitz, M.D.

No. IV. The Statistical Experience Data of the Johns Hopkins Hospital, 1892-1911. By Frederick L. Hoffmann, LL.D., F.S.S.

No. V. The Origin and Development of the Lymphatic System. By Florence R. Sabin. Baltimore: The Johns Hopkins Press. 1913.

These five large pamphlets represent the beginning of a new series of publications by the Johns Hopkins Hospital. They are all monographs of research.

Dr. Hewitt, from his study of cardiac thrombosis, concludes that no practical treatment different from that ordinarily employed in mitral stenosis with insufficiency can be recommended.

Dr. Selling, from his studies on the degeneration and regeneration of the blood and hematopoietic organs, concludes that benzol is a powerful leucotoxin, destroying the white cells of the circulating blood and the parenchymal cells of the hematopoietic organs. Myeloid tissue is injured more than lymphadenoid tissue, and polynuclear leucocytes more than lymphocytes. The erythroblastic tissue of the bone marrow is destroyed, but the circulating erythrocytes are injured relatively little. By repeated injections of benzol, the myeloid and the lymphadenoid tissues can be rendered almost wholly aplastic.

Dr. Winternitz reports four cases of primary carcinoma of the liver. It is rare, occurring only in from 0.03 to 0.3 per cent. of all autopsies. It occurs most frequently in adult males, and clinically is difficult to differentiate from cirrhosis.

Mr. Hoffmann's elaborate statistic study concludes with high praise for the excellent record system of the Johns Hopkins Hospital. He believes, however, that the Bellevue Hospital method of classification is preferable.

Miss Sabin, from her embryologic study of the morphology of the lymphatic system, finds that lymphatic capillaries are tubes of endothelium, derived from the veins, and having the same relation to tissue spaces as have the blood capillaries.

Time and the Timeless. Songs of Shadow and of Hope. By a Physician. London: Henry J. Glaisher. 1914.

This is a small, paper-covered volume of verse by a physician who, though nameless is apparently a Scotsman. It consists of a number of brief poems and one somewhat longer piece, "To a Brother Physician." So far as these deal with medical topics (as in the unfortunate lines on "This Little Bistoury"), they can hardly be called successful. Indeed Mr. Kipling is probably today the only living man who could make poetry out of such material. Some of the other verses, however, apart from professional experience, have a more genuinely lyric character. The best of these, "In the Fratry of Furness Abbey," may serve as an example of all.

"Thy walls are desolate, and where
The gownèd monks sat, row by row,
Tall trees their shadowy foliage throw
And toss their branches high in air.

"The broken pillar, the noble arch,
The square red stones, pil'd huge and high,
As rugged time-worn tokens lie,
Marking the Day's triumphant march.

"No longer shut in walls of stone
The highest thoughts of men are pent,
But, bursting earthly tenement,
They claim the heavens for their own."

Communicable Diseases. By J. W. Kerr, Assistant Surgeon-General, and A. A. Moll, A.B. Washington: Government Printing Office. 1914.

This volume, prepared by direction of the surgeon-general and issued as a public health bulletin (No. 62) by the Treasury Department, is an analysis of the laws and regulations in force in the United States for the control of communicable diseases. It is intended as a sequel to bulletin No. 54, which described and commented upon the provisions governing health organization in this country. The first portion consists of a discussion of the principles involved in the prevention of disease; the second is an appendix of miscellaneous matters; the third presents the text of federal, state, and territorial laws on the control of disease. The book is a valuable repository of important information, and should prove useful to students of preventive medicine.

The Anatomist's Notebook. A Guide to the Dissection of the Human Body. By A. Melville Paterson, M.D., Edin., F.R.C.S., Eng. London: Henry Frowde, and Hodder and Stoughton. 1914.

This volume, in the series of Oxford Medical Publications, is essentially a dissecting syllabus. The text provides a summary of structures to be investigated, and the intervening blank pages afford opportunity for laboratory notes. There are 26 outline diagrams for original drawings. The book should be of convenient value to elementary and advanced students of anatomy.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JUNE 4, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE NEUROLOGICAL INSTITUTE OF NEW YORK.

THE fourth annual report of this institution, recently issued, shows a continuation and expansion of the excellent work in which it has been engaged since its organization and contains much that is of practical as well as scientific interest. The real need in a large city of such a hospital, affording the most skilled modern treatment in its special department, is shown by the material increase in the number of patients cared for; nearly 500 more having been admitted to the hospital wards, and nearly 600 more to the dispensary, than in 1912. Considering the very limited capacity of the institution, the number of treatments given has been remarkable for during the past year the individual treatments in the dispensary alone amounted to nearly 30,000. The order of popularity of these, it is stated, has been: electrotherapy, hydrotherapy and massage. Mechanotherapy, was the least popular of all.

In preceding reports mention was made of the good effects of the hospital treatment of persons merely threatened with some mental disorder. A continuance of these beneficial results has been noted, and it is felt that the institute, if it had done nothing else, has justified its existence by the good it has done in this way. By this prophylactic management the development of insanity has frequently been arrested, and individuals so threatened have been enabled to return to their work after a short time, instead of being condemned to a long period of mental disturbance. In two diseases the benefits of the special equipment and methods employed have been particularly manifested, chorea and poliomyelitis. In the former, isolation and quiet have proved very successful, and in the after-treatment of poliomyelitis admirable results in the way of prevention of permanent paralysis are accomplished by the judicious use of massage and electricity—a form of treatment to which scant attention is apt to be given in general hospitals.

Particular attention is called to the report of operations performed during the year. The skull was opened thirty times for various diseases, with a mortality of four.

A large portion of the report is taken up with the work of the department of social research. The most important of its problems is stated to be that of personal advice and instruction. The results of the examinations belong to the physicians, who determine the diagnosis and treatment; but in a large number of instances the explanation and oversight of the treatment prescribed are entrusted to the examiner, who has made the long personal inquiry and has an intimate knowledge of the factors in the case on which successful treatment depends. As to the problem of the individual, the more intimate phases of the work are found hard to describe without violating the confidences of the examination room, but illustrations are given which are typical of the ordinary run of cases. The following are the problems mentioned, illustrative cases being cited in each: 1. Problems of fear in young men and women. These frequently present themselves in the form of slight alterations in physical condition, associated with unreasonable concern about health, mental adequacy, or business or social success. 2. Problems of waywardness in childhood—sometimes due to inherited weakness and sometimes merely the accompaniment of some passing disorder; or they may be traced directly to bad care or to a bad example in the home. 3. Problems of waywardness in youth. Flagrant waywardness of conduct has been brought to the attention of the service much more commonly in the case of young women. 4. Problems of retardation and of special guidance. Whenever retardation in school studies is due to settled deficiency it is regarded as important to discover it in time and to obtain some clear idea of its nature and possible consequences; and equally important to estimate

clearly the nature of any special aptitude and establish the conditions under which it may be developed. 5. Problems of special defect. The largest number of such cases have been in those suffering from some form of speech defect. During most of the year a class has been conducted in speech training—individual lessons being given; and in every instance where the attendance has been regular very satisfactory progress has been made. Very many of the cases referred to this service were accompanied by a definite request for some estimate of the patient's general efficiency, and in the department it has been found that success or failure in dealing with patients commonly turns on an accurate estimate of their efficiency. At first this situation was met by selecting from the growing literature of tests any that seemed adapted to the particular case under observation, but gradually a number were selected as being particularly suitable for a neurological clinic. During the past year this work with tests has taken the form of trying out a set of tests for the pre-adolescent period, and this has been given in its complete form to over 250 individuals and in partial experimental form to as many others. In the report there is presented the scheme followed in the arrangement of tests for all the growth periods, as well as a table of tests selected, in accordance with this scheme, for the pre-adolescent period.

The hope is expressed by the medical board that sooner or later the scope of the work of the institute will be greatly expanded. It should be its aim, to discover the causes of nervous and mental diseases, to suggest remedies which will affect the race as well as the individual, and to disseminate such knowledge. To attain this goal, part of the working force must be directed to pure science, which would demand an equipment far different from that at present possessed. Such an institute, to which physicians and all concerned with education and public health would naturally turn, as they turn now in the matter of infectious diseases to the Rockefeller Institute, would be an incalculable benefit to the community.

Maine Health Ordinance.—The Maine State Board of Health recently adopted a regulation, which became operative on June 1, forbidding the use of common drinking-cups and roller-towels in schools, hotels, restaurants, railroad trains and other public places and conveyances.

THE MEXICAN SITUATION.

During the active progress of mediation at the conference now in session at Niagara Falls, Canada, hostilities continue between the contending Mexican factions. Tampico has been seized by the constitutionalists under General Villa, and has been made a basis of further operations against Mexico City. Meantime the United States forces hold a position of neutrality in occupation of Vera Cruz. General Funston, who is in command at that city, reported on May 22 a sick rate of 1.49% among the soldiers and 1.46% among the marines quartered there. Smallpox has already been almost wholly eradicated from the city. The United States has a total fleet of 34 warships lying off Vera Cruz and 17 off Tampico.

In the issue of the Journal for May 21, we referred editorially to the absence of the hospital ship *Solace* from Mexican waters during its voyage to New York for transportation and repairs. It appears that at least one other hospital ship is much needed by the navy.

"The Navy Department has had under consideration the purchase of a vessel in New York suitable for the purpose, but the owners of the ship have demanded $1,000,000,—a price regarded by the department officials as excessive. It is hoped that further negotiations with the owners will result in a reduction, but there are some naval officers who believe that the necessities of the case justify its immediate purchase, as a delay might result in increasing the number of deaths. The vessel in question would require an expenditure of $125,000 to fit out as a hospital or ambulance ship.

"Two vessels are declared necessary—one to remain in the neighborhood of Vera Cruz while the other is transporting the sick and wounded away from the tropics. Unless this is done, as is recommended by the surgeon-general of the navy, with the approval of the army medical officers, it is apprehended that there will be disasters which will arouse public criticism of the Administration. Secretary Daniels believes that there is no necessity for immediate action, and has informed his assistants in the Navy Department that he does not propose to be held up by ship owners because of the apparent necessity for a special type of ship."

It is to be hoped that neither motives of false economy nor an undue sense of security in the present situation may be allowed to prevent the immediate obtainment by the navy of a proper ship for the purposes required.

JULIUS BETTINGER "(L'ANONYME DU PALATINAT)".

FOR half a century or more the identity of the physician who, under the above title, contributed so much to the knowledge of the experimental inoculation of syphilis remained a complete mystery. It was in 1855 that the experiments were reported to the Medical Society of the Palatinat according to a recent article in *La Chronique Médical*. The experiments proved irrefutably the contagious properties of specific blood, as well as secondary specific lesions. This was at the time that Ricord held diametrically opposite views on this subject. It was, according to this article, Hoffmann's researches into the question of the infectivity of specific blood and his study of the older literature pertaining to this question which led him to the discovery of the author of these experiments heretofore shrouded in mystery. In the *Aertzlicher Intelligenz-Blatt* for 1856, the article goes on to say, he found the report of the proceedings of the Society of the Palatinat pertaining to this work. ("Rapport Médical pour le Palatinat rédigé d'après les Rapports Médicaux de Cantons.") The identity of the author was made certain by a communication from the son of Bettinger to Hoffmann.

Bettinger was born in 1802 at Zweibsucken, and studied medicine at Wurzbourg; at 22 years of age he was named assistant at the Cantonal Hospital at Frankenthal in the Palatinat. It was here that in later years his communication regarding the inoculability of specific blood and secondary lesions was made. In 1836 he was created director of the Cantonal Hospital; in 1856, one year after the anonymous communication had appeared, he received the Cross of the Order of St. Michael, without there being any apparent explanation of this honor. In 1878, his 50th anniversary of service in the Palatinat was celebrated, and he was the recipient of many tokens of respect and esteem for his life-long service and high attainments. He resigned in 1885 and died in 1887, having preserved his pristine vigor and strength of mind and body till nearly the end, also having kept the authorship of his chief work secret. It is of exceeding interest that Hoffmann, one of the discoverers of the cause of syphilis, should be the observer to throw light on the long puzzling question of the identity of "l'Anonyme du Palatinat."

ANOTHER MARINE TRAGEDY.

THE sinking of the Canadian steamship *Empress of Ireland*, off Rimouski in the Gulf of St. Lawrence early on the morning of May 29, with a loss of very nearly 1000 lives, vividly recalls the *Titanic* disaster of April 15, 1912. The *Empress*, while lying to in a fog, was rammed amidships about 2 a.m. by the Norwegian collier *Storstad*, and sank in 14 minutes. Many passengers were crushed to death in their berths by the impact of the collision. Many others were drowned when the ship went down. There was not time to man but a few lifeboats. About 400 persons were picked up by the *Storstad* and by the *Lady Evelyn*, which was summoned by wireless to the scene of disaster. Some of those rescued subsequently died of shock, exposure, or injuries, and many of the survivors are suffering from fractures and other trauma. Among those who perished was Dr. M. A. Lindsay, pathologist at the Victoria General Hospital, Halifax, N. S., who was on his way to England to be married.

Especial praise is given by surviving passengers to the ship's surgeon of the *Empress*, Dr. James F. Grant, of Victoria, B. C., a graduate of McGill University Medical School in 1913. Coming on deck from his cabin after the collision he coolly directed the embarkation of passengers and assisted in the launching of several lifeboats. When the vessel sank he swam to one of the *Storstad's* boats, which had put out, superintended the rescue of many persons from the water, and subsequently for hours aboard the *Storstad* devoted himself to the relief and treatment of the injured. Amid the melancholy reflections evoked by such a tragedy, it is an encouragement to find that the fine ideals of valor and service were so well maintained by this young representative of our profession.

MEDICAL NOTES.

VON BEHRING'S NEW DIPHTHERIA SERUM.—Report from Berlin on May 23 announces that von Behring's new toxin-antitoxin diphtheria serum is soon to be placed on the market for use as a durable immunizing agent against diphtheria. Excellent results from its use have been reported in the German medical journals.

A NEW INDIAN SCHOOL OF TROPICAL MEDICINE.—A recent item in the *Scientific American* calls

attention to the new Calcutta School of Tropical Medicine, whose corner-stone has just been laid by the lieutenant-governor of Bengal.

"This school will have unique advantages for carrying on its special line of work, viz., the study of tropical diseases, with a view to finding more accurate methods of diagnosis and treatment. Such diseases are responsible for more than one-third of the mortality in the city of Calcutta. From the consul's report it appears that the new institution aims to become an international centre in its particular field; students will be welcomed from all parts of the world, and medical research institutions in other countries are urged to establish scholarships at the Calcutta school, or to provide otherwise for sending research students to enjoy the advantages it offers. Inquiries should be addressed to Lieutenant Colonel Leonard Rogers, I. M. S., Medical College, Calcutta."

BUBONIC PLAGUE IN HAVANA.—Another case of bubonic plague was reported at Havana on May 25, making a total of 20 since the outbreak of the present infection. There have thus far been three deaths of the disease. The city is quarantined.

BOSTON AND NEW ENGLAND.

SCARLET FEVER AT MILTON ACADEMY.—The epidemic of scarlet fever at Milton (Mass.) Academy, which we noted in last week's issue of the JOURNAL, has extended. There are now 30 cases among students and the institution has been closed and quarantined.

APPEAL OF BABY HYGIENE ASSOCIATION.—In a recent bulletin, the Boston Milk and Baby Hygiene Association has appealed to the public for $2000 to provide six additional nurses for carrying on its work during this summer.

A CENTENARIAN.—In the issue of the JOURNAL for June 20, 1912 (Vol. clxvi, p. 943), we chronicled the supposed centennial anniversary of Mrs. Benjamin de St. François, of Medford, Mass., said to have been born on June 12, 1812, at Chambley, near St. Francis, P. Q., Canada. We regret exceedingly to learn of her recent death, on May 21. Of her seven children, she is survived by three aged daughters; also by three grandchildren, and three great-grandchildren. She had been a widow since 1850.

WASSERMANN AND SCHWARTZ TESTS IN BROOKLINE.—The Brookline (Mass.) Board of Health has just announced, in a circular letter to physicians, its preparedness to do Wassermann and Schwartz tests free of charge.

"The Brookline Board of Health desires to call to the attention of physicians the fact that it will make free of charge for residents of Brookline the Wassermann test for syphilis and also the corresponding test for gonorrhea, the so-called complement fixation test.

"The necessary outfits for these examinations may be had at the Board of Health Laboratory in the Court House on Prospect Street. Specimens for the test for syphilis may be sent to the Laboratory on any week day except Friday and Saturday. For the blood test for gonorrhea a special arrangement must be made by communicating with the Laboratory.

"Physicians are required to fill out a card giving certain information in regard to the case, but they need not give the name of the patient, provided they will sign a statement that the patient is a resident of Brookline, and will substitute letters or numbers for the name to identify the specimen. The same letters or numbers should be used for subsequent specimens from the same individual.

"For the present, these examinations will be made at the Laboratory of Neuropathology at the Harvard Medical School.

"The Board of Health is undertaking to furnish these examinations because it believes that the more frequent use of the tests will result in preventing the spread of these serious communicable diseases and will also enable physicians to recognize and successfully treat syphilitic lesions of many different organs of the body."

The remainder of the circular describes the uses and interpretation of the Wassermann reaction and the complement fixation test for gonorrhea, and gives instructions to patients and directions for collecting blood for the tests.

BOSTON CITY HOSPITAL TRAINING SCHOOL.—The annual graduating exercises of the Boston City Hospital Training School for Nurses were held in the surgical amphitheatre on Friday afternoon, May 29. The principal address was made by Mayor Curley, who distributed diplomas to 43 graduating nurses.

HOSPITAL BEQUESTS.—The will of the late Frances H. Curtis, of Jamaica Plain, Mass., which was filed on May 23 for probate in the Suffolk Registry, contains a bequest to the Faulkner Hospital of $8000 to constitute a fund for the maintenance of a free bed to be named after George S. Curtis.

The will of the late James Sagebury, of Arlington, Mass., which was filed on May 26, at

the probate court in East Cambridge, Mass., contains contingent bequests of about $5000 each to the Infants' Hospital, the Children's Hospital, the Samaritan Hospital, the Lying-in Hospital, and the Woman's Charity Club Hospital, of Boston, and the Free Hospital for Women, of Brookline, Mass.

MASSACHUSETTS MEDICAL SOCIETY.—The one hundred and thirty-third annual meeting of The Massachusetts Medical Society will be held in Boston on Tuesday and Wednesday of next week, June 9 and 10. The sessions will be at the Copley Plaza Hotel and the Massachusetts General Hospital. The Shattuck Lecture will be delivered by Dr. Herbert C. Moffit, of San Francisco, and the annual discourse by Dr. Horace D. Arnold, of Boston. The annual dinner will be at 7 p.m. on June 10.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending May 26, 1914: Diphtheria, 47, of which 1 was non-resident; scarlatina, 120, of which 25 were non-residents; typhoid fever, 10, of which 2 were non-residents; measles, 144; tuberculosis, 68, of which 2 were non-residents.

The death-rate of the reported deaths for the week was 15.00.

NEW YORK.

MORTALITY FOR THE WEEK ENDING MAY 23, 1914.—There were 1592 deaths and a death-rate of 14.88 per 1000 of the population reported during the past week as against 1572 deaths and a rate of 15.27, an absolute increase of 20 deaths, and a decrease of .39 of a point in the weekly rate, equivalent to a relative decrease of 42 deaths.

The following causes showed an increased mortality: Measles, diphtheria and croup, typhoid fever, diarrheal diseases under five years of age, tuberculous diseases other than pulmonary and violence. Those causes showing a decreased mortality were scarlet fever, influenza, acute respiratory diseases and pulmonary tuberculosis. The mortality from whooping cough, organic heart diseases, Bright's disease and nephritis and nervous diseases were approximately the same as that of last year.

Viewed from the point of age grouping the mortality of infants under one year of age was slightly in excess of the figures of last year, while that of infants between one and five years was approximately the same. The mortality between five and sixty-five years of age was decreased somewhat, and that of sixty-five years of age and over was considerably increased.

The death-rate for the first 21 weeks of 1914 was 15.33 per 1000 of the population as against 15.55 for the corresponding period of 1913, a decrease of .22 of a point.

HONOR FOR DR. JELLIFFE.—Dr. Smith Ely Jelliffe, of New York, has been made a corresponding member of the Paris Neurological Society.

THE MENACE OF CANCER.—In view of the undoubted increase in the mortality from cancer, the Department of Health is seeking in every way to educate the general public regarding the nature of this terrible malady and as to the surpassing importance of early recognition and treatment. It is usually not known that the general death-rate of persons over 40 years of age *is higher* now than it was thirty years ago. In this increase, in addition to diseases of the kidneys, heart and blood vessels, cancer plays a large part.

While the ultimate cause of cancer is not yet known, much has been learned about conditions giving rise to the disease. Among these some form of chronic irritation ranks first. Physicians have also come to recognize what are termed "pre-cancerous" conditions." Prompt surgical attention to such conditions will do much to prevent cancer. Competent surgery in the early stages means a large percentage of cures, and the earlier the better. Hope lies chiefly in the first operation. Delay means not simply danger, but as a rule, inevitable death.

X-rays and radium are often valuable adjuncts to surgical treatment, but alone they are useful only in the skin cancers and other superficial forms. In Europe, where the popular furore about radium appeared earlier than in this country, great numbers of dishonest and fake, money-getting, radium-cure establishments have made their appearance. There is danger of the same thing occurring here, unless the public heed the warnings of competent authorities.

The evidence so far collected on early cancer also brings a message to the people who seek help in the later stage of cancer. Although the chances of a cure here are less, the disease in many instances is by no means hopeless. Even when the hope of cure is remote, surgery looks

toward the prolongation of useful life and the relief of much suffering.

Not only the public, but the medical profession, needs education with more reliable data as to the results of early diagnosis and treatment. The diagnosis of cancer, in its earliest stages, when treatment gives the very best results and the greatest number of cures, is more uncertain, and the treatment in this stage, although very much less dangerous, is a more delicate surgical procedure.

Typhoid in Brooklyn.—On May 23 the Health Department issued an official report in regard to the Mercer family in Brooklyn, two children in which became seriously ill after antityphoid vaccination. This was done by the family physician, at the request of Mr. Mercer, who was suffering from typhoid fever and later succumbed to the disease, and the vaccine was procured from the Health Department office in Brooklyn. The report states that the children are affected with typhoid fever, but that this must have been contracted before the vaccination, and not as a result of the latter. One of the children was thought to have cerebrospinal meningitis, but it was found that the symptoms pointing to this were due simply to pressure from cerebrospinal fluid. No meningicocci were found in the fluid, and the removal of some of the fluid by the lumbar puncture markedly benefited the patient. A third child, as well as the mother and an aunt, who were vaccinated at the same time, are now entirely well.

Investigation by Health Department.—A study has recently been made by the Health Department to ascertain what proportion of secondary cases follow the various contagious diseases when the patients are treated at home and when they are removed, with the following results: Diphtheria, quarantined at home, 13%; removed to hospital, 1%. Scarlet fever, quarantined at home, 9%; removed to hospital, 6%. Measles, quarantined at home, 14%; removed to hospital, 4%. A plan has been developed for the better supervision and treatment of cases of whooping-cough by the hospitals and dispensaries of the city. The department is taking up the matter with the Associated Out-Patient Clinics and the hospitals, and it is hoped that before long adequate facilities for the care of such patients will be provided.

1. Friedman has found polycythemia of value in the differential diagnosis of duodenal ulcer, especially from gastric ulcer and chronic appendicitis. There is no pathognomonic symptom of duodenal ulcer, he says. The history is important, especially a history of hunger pain, late pain and night pain, but atypical histories are common. The x-ray is very valuable, but the value of this, too, is limited. The data obtained by analysis of the duodenal contents is of secondary importance. In his cases, in all of which diagnosis was confirmed at operation, he found polycythemia almost constant in non-hemorrhagic duodenal ulcer, and in many instances it was the only distinctive feature. The average hemoglobin in his series was 90%, the average red count 5,921,000, the average white count normal. In gastric ulcer and chronic appendicitis a varying degree of secondary anemia is the rule. [L. D. C.]

1. Patrick finds pure trifacial neuralgia about evenly divided between men and women, and not more common in women, as Dana has believed. As to age, it is more common in the degenerative period of life. More than half of the author's cases have been between 40 and 60 years of age. The impression exists that these patients are of the neurotic type, but Patrick does not find this borne out. Only one of his 220 cases really contracted the morphine habit. The right side is always more commonly affected than the left. The author offers no explanation for this. Patrick differs with most other writers in regard to the location of the pain. He believes the second division, not the first, is the most common location. The pain is essentially short-lived. Any pain about the face, forehead or temple which is a steady ache, which is continuous for a half hour or more, is not trifacial neuralgia. The disease is essentially chronic with no tendency to recover. The element of tic or motion is not a part of true trifacial neuralgia. Syphilis as an etiologic factor is noticeable by its rarity. Patrick does not believe in the toxic theory of its cause. This article is of very practical value and worth reading.

2. Nichols believes that a strictly medical campaign against syphilis is neither practical nor desirable. A modified medical campaign is both practical and necessary. The prevalence of the disease is still largely a matter of conjecture. The most hopeful outcome of all the recent work on syphilis is the possibility of an early diagnosis and radical cure. Our ideas about the efficiency of treatment and a standard of cure are more definite but need further elucidation. Syphilis is in most cases a preventable disease and this fact is an additional warrant for penalizing those who contract it.

8. Stevens favors the phloridzin test as more accurate than the phenolsulphonephthalein test in kidney function. It also takes less time.

4. *SMITH, W. M. *Meningitis in Children.*

1. Stewart believes that before coming to any definite conclusion concerning prognosis or course of treatment of any case of cerebro-spinal syphilis prolonged observation and study are necessary. Only cases in the early stages should be selected for radical treatment before the cortex has become profoundly degenerated. He believes in a combination of intravenous, intraspinous, intracranial treatment. While possibility of a cure is slight, alleviation and arrest to a greater or less degree may be possible in those cases. The writer presents details of cases and methods used.

4. Smith discusses the various forms of meningitis in children and their diagnosis and treatment. The whole subject is clearly shown in tabular form.

14. ELDER, G. T. D., *and* DANKIELS, D. *Case with Comments. Pancreatic Hemorrhage.*

1. Savage discusses in a general way the relationship of syphilis to insanity in its various forms and comes to the natural conclusions that syphilis may be a cause of congenital mental defects and undoubtedly is the cause of general paralysis and other similar conditions. He believes in treating such patients with salvarsan, but does not hold out much hope as to a cure.

2. This is a good review of the subject of digitalis and its value in various forms of heart disease, but presents nothing new.

3. Cammidge, in a long paper, takes up the relation of glycosuria to disease of the pancreas. He discusses at length the work of other investigators and the historical side of this complex subject and its physiology and pathology. He believes that in the case of death from persistent glycosuria, pathological changes can be demonstrated in the pancreas in 70-80% of the cases; it does not follow that lesions of the pancreas are the primary cause of the condition in that proportion of cases. He describes his own investigations on this subject and gives the details of the various tests he has elaborated. He urges early treatment along scientific lines for every case of glycosuria, even of an apparently mild and simple character. It is pure empiricism to place a patient with glycosuria on a carbohydrate-free diet without further investigation. Other facts concerning metabolism in general should be ascertained in every such case.

4. Blaxland discusses gall-stone disease from various points of view as to symptoms, diagnosis, treatment, results of operation, etc. His paper is based on a study of 116 consecutive cases.

6. This is a good clinical study of the various causes of anemia in childhood and their cure and prevention. [J. B. H.]

4. Nakano reports a case which, clinically, had the weakness, malaise, vomiting and diarrhea characteristic of hemochromatosis. At no time, however, during a long period of observation was sugar found in the urine. At autopsy changes were found in the liver, spleen, and pancreas, which justified the diagnosis of hemochromatosis. The adrenal glands appeared normal.

Cases of hemochromatosis without glycosuria have been described, as well as cases of this disease combined with atrophy of the adrenal glands. Nakano concludes that his case must be considered glycosuria, and with symptoms of severe auto-intoxication due to a functional adrenal insufficiency.

11. In No. 13 of this periodical Scharnke objected to the bath treatment of delirium tremens. Schneider in reply records 31 cases which occurred in the city hospital of Köln during the year 1913. The cases were all of outspoken alcoholic delirium, and were treated in the same fashion. There was not a single death despite such complications as bronchitis, pleuritis, pneumonia, erysipelas and senility.

The method of treatment employed consisted in the use of a continuous warm bath without restraint. As soon as the patients became sleepy, they were placed in bed. Alcohol and hypnotics were never used. When the heart showed danger of collapse it was stimulated with digitalis, camphor or caffein. Such treatment, however, was necessary in only two cases of Schneider's series.

Schneider concludes that this communication offers evidence in support of the hydrotherapy of delirium tremens. [R. F.]

1. Wechselmann is one of the few men who advise the use of salvarsan alone, that is, without combining it with mercury. He has carried out this treatment exclusively for four years with excellent results, giving in some cases as many as 35 or 40 doses in a single case, and recently having used neosalvarsan. He has given 45,000 injections without a death, and claims first that the fatal results are usually due to lack of appreciation of contraindications, and second that untoward effects are much more liable to occur when mercury is being used at the same time. Of interest in regard to deaths are the statistics of Leredde, quoted by the author, to wit:

Year	Deaths	Salvarsan Injections
1910	16	50,000
1911	92	800,000
1912	66	1,200,000
1913	37	2,000,000

These demonstrate clearly lessened fatalities as clinicians become more familiar with the drug.

2 and 3. These two authors sum up various points of interest in regard to modern treatment, disagreeing with Wechselmann in his conclusions as stated above, that salvarsan alone is the best treatment. Blaschko (2) especially states that Wechselmann lost sight of numerous cases which were really not cured, but turned up at other hospitals and were given combined treatment.

5. Post presents a case of pernicious anemia operated on (splenectomy) in December, 1913, and already showing marked improvement. Before opera-

tion the highest red count was 1,600,000, and on March 11, 1914, it had risen to 3,556,000, and the hemoglobin had gone from 50, its highest point before operation, to 77. The case to date had been observed only three months after operation, but the beneficial results seemed striking. [R. H. M.]

1. Citron emphasizes the importance of beginning anti-syphilitic treatment as soon as possible, and following it up energetically as long as any traces of the disease persist. He thinks that many late syphilitic lesions are due to improper treatment of the earlier stages by dermatologists, and is especially anxious that it should no longer be considered a skin disease. He favors combined treatment, and does not put much trust in Wechselmann's method of using salvarsan without mercury.

[R. H. M.]

Miscellany.

A PRACTICAL METHOD OF DRYING CULTURES OF BACTERIA.

ALL the better class of creameries use for ripening cream pure cultures of bacteria which are obtained at regular intervals from commercial laboratories. These are carried in the creameries by transferring milk cultures from day to day, the culture being renewed occasionally to insure its purity. The small milk culture, known as a "mother starter," is usually carried in bottles or small jars, from which it is transferred to a large can or vat of milk to make the starter used to ripen the cream.

The ideal culture for distribution is in a dry form, sufficiently active to produce rapid growth when it is added to milk and yet so dormant that it can be held a long time without losing its activity. But the difficulties of producing a culture in this condition are so great that the most successful of the commercial cultures are distributed in a liquid medium and must be used within a comparatively short time. A few cultures, however, have been sold continuously in a powder or tablet form; in other cases the liquid culture has been found to be more satisfactory and the dry culture has been abandoned.

Recently the general interest in fermented milks, especially those of the Yoghourt type, has stimulated the production of various kinds of tablets and capsules which ostensibly contain the organism in such quantities that the culture can be used to start a fermentation in milk or to inoculate the digestive tract by direct consumption. These cultures, as well as those sold for butter-making and cheese-making, are of real value only when they contain a suitable organism free from contamination and are sufficiently active to start the acid fermentation before accidental contamination can develop to an appreciable extent.

As a result of recent experiments the Dairy Division of the Bureau of Animal Industry, United States Department of Agriculture, has devised a method of drying cultures by which the loss in bacterial content is greatly reduced. Experiments in removing the water by a spray carried up by a current of warm dry air were found to produce satisfactory dry cultures, but rapid drying by this process requires the use of complicated and expensive machinery not within the reach of the ordinary laboratory.

Cultures were then successfully evaporated by freezing and lowering the atmospheric pressure. Phosphorus pentoxid and lime were used to absorb the moisture, but sulphuric acid proved to be the best agent for this purpose.

These experiments show conclusively that water may be removed from cultures of bacteria used in the manufacture of dairy products by exposing them in a frozen condition over sulphuric acid in a vacuum approximating 0.01 mm.

Fresh lactic cultures dried by this method are sufficiently active to curdle milk in 17 hours at 30° C. when added in the ratio of 1 part of powder to 1,000,000 parts of milk.

The total number of bacteria in a milk culture may be increased by adding dibasic potassium phosphate, but the powder made from the culture is less active than that made from unneutralized milk. The activity of the powder is not increased by neutralizing the culture with calcium carbonate before drying.

More powder may be produced at each operation of the drier by using a culture grown in milk concentrated to one-half its original volume, and this powder is as active as that made from normal milk.

The activity of a dried culture diminishes more or less rapidly, depending on the conditions under which it is held. The loss of activity in powders is much more rapid when the moisture content is comparatively high. The loss in activity is very slow at 0° C. or lower, and becomes more rapid as the temperature is increased. Dried cultures of the lactic acid bacteria held at 30° or 37° C. become inactive in a short time. Cultures held in a vacuum retain their activity much better than cultures in an atmosphere of

nitrogen or hydrogen; the most rapid loss of activity takes place either in air or in an atmosphere of oxygen.

Very active dried cultures of *bacillus bulgaricus* may be made by the freezing-vacuum method; they curdle milk in 20 hours at 37° C. when added to milk in the ratio of 1 to 100,000.

UNITED STATES MORTALITY STATISTICS.

FROM a statement recently published at Washington by the census bureau, it appears that the death-rate in the registration area of the United States in 1913 was 14.1 per 1000.

"This figure of 14.1 as the death-rate for 1913 was based on 890,823 deaths returned from 24 registration states, the District of Columbia and 41 cities in non-registration states. The total population included in the registration areas reporting is 63,299,164, or 65.1 per cent. of the estimated population of the United States. While the figures are not complete for the entire country, they serve as an index to the general sanitary condition of the United States. Virginia is included for the first time in the national vital statistics, as the result of the passage of a registration law in that state in 1912, and the Bureau of the Census is actively cooperating with officials in other states so that the entire country may be included in the area having effective registration at the earliest possible date.

"The death-rate for 1913 (14.1 per 1000) slightly exceeded that for 1912, which was 13.9, but was less than that for 1911, which was 14.2. It also is markedly lower than the average rate for the five-year period 1901-1905, which was 16.2. The decrease in the death-rate amounts to 13%, or to a reduction of about 1 death in every 8, during the interval of ten years. Allowing for changes made in the registration area during this time (much new territory has been added), when comparison is made of the rate shown for 1913 and for 1901 to 1905, with the same group of registration states, there is still a considerable decrease shown (7.5%). If the same death-rate had prevailed in the registration area in 1913 as prevailed in the annual average for the years 1901-1905 there would have been 1,025,446 deaths recorded instead of 890,823, an excess of 134,623 over the number recorded in 1913. In the original group of registration states as constituted in 1901-1905, the population of which is about one-fourth of the total population of the United States, the reduction in mortality would have been equivalent to a saving of 30,546 lives in 1913 that would have been lost if the former rate of mortality had continued.

"Among the states for which the death-rates for 1901 to 1905 are given, the largest percentage of decrease was shown for Rhode Island (15.7), followed by New York (12.3), New Jersey (11.2), and Massachusetts (9.6). Slightly increased death-rates for 1913 are shown for Michigan (4.5), New Hampshire (3) and Indiana (0.8). These increases may be due in some cases to increased accuracy of registration of deaths during 1913 as compared with the earlier period.

"Among the cities of 100,000 population and over the variation shown in the death-rates covers a wide range. In general, the tendency seems to be to a lower mortality. The following cities show a reduction of 20% or more from 1901-1905 to 1913, or an average of 2% or more for each year of the past decade: New York, 24.7; Jersey City, 24.4; Newark, N. J., 23; San Francisco, 21.7; Lowell, Mass., 21.3; Spokane, Wash., 21.2; Denver, Col., 20.3, and Paterson, N. J., 20.1."

Correspondence.

REORGANIZATION OF THE STATE BOARD OF HEALTH.

BOSTON, May 28, 1914.

Mr. Editor: With the retirement of Dr. Henry P. Walcott from the State Board of Health the health matters of Massachusetts may be said to have come to the "end of an era." It has been his forethought and wisdom that has brought Massachusetts well to the forefront of the states in health matters. Of those who have worked with him in the past only Mr. Mills remains. All of the other members of the Board are serving their first term so that it will be seen clearly that the retirement of Dr. Walcott puts the state health department in new hands.

To those who have realized what was to happen it has long been evident that there was no Elisha on whom could fall the mantle of the leader. This was fully realized by Governor Walsh on taking office and by Dr. E. H. Bigelow, the House Chairman of the Public Health Committee, and they immediately after election took council together as to how they should meet the emergency. Crude bills for the reorganization of the State Board of Health appeared in the legislature, which the Legislative Committee of The Massachusetts Medical Society opposed. In order to try and help matters along they suggested to the Public Health Committee that any reorganization that might be made, should be with a Commissioner of Public Health to be in charge of the executive work of the department, to control and direct its machinery with departments more distinct and better defined than at present and further an advisory council to protect the public from autocratic action on the part of the commissioner, and to give him advice in the formulation of rules under which he shall work, thus preserving, as far as possible, the Massachusetts idea of an unpaid board. This JOURNAL early in the year advocated this general line of action.

The present bill (House No. 2598) which was printed in full last week together with the Governor's message is along these lines. It was arrived at after many hours of consultation between the Governor, Dr. J. W. Kerr, Asst. Surgeon-General of the United States, The Public Health Committee, Dr. M. J. Rosenau and others. The drafting was finally left to Dr. Rosenau after the general features were decided upon. It was then carefully studied by the Governor and various physicians who were invited to meet and confer with him.

The bill carries out the general scheme for a Commissioner devoting his whole time to the health matters of Massachusetts who shall be at the State House and meet the people and also go out to study the problems as they present themselves in our densely populated state. The Health Council is to carry on the judicial work of the present board and to draw health rules for the state, under the laws, which shall apply throughout the Commonwealth. The district health officers who on part time have developed into a strong and important body of men, helpful throughout their district, have been strengthened by putting them on whole time although reducing their number.

When one looks at the past events one has to realize that although the present State Board has been an unpaid board, nevertheless the chairman has had a salary from the state, although in another capacity. Though it has been a painfully inadequate salary for all the services rendered to the state it has nevertheless been a salary and any competent new man coming to the service of the state, whether from the ranks of the state medical profession or called from abroad, would have to be provided with a living. Hence the necessity of providing the man on whom are to devolve the responsibilities of the present chairman and the difficulties of taking up a new work with a salary. Seventy-five hundred dollars may not seem a sufficient recompense but no state excepting Pennsylvania at present pays a ten-thousand dollar salary for its chief health officer. State and university work are notoriously underpaid.

There are two methods of drawing a bill, one which takes every possible detail into consideration and tries to incorporate it into law, the other which tries to establish the broad general principles which it is desired to elaborate, leaving the detail to the executive to work out. Of the former the health law of New York with its 22 pages is an example. There is a mass of health legislation in Massachusetts, which must be lived up to. What suggestions the present State Board of Health may have had regarding it are not known, for the codification of the health laws and the board's suggestions for new legislation, not having been presented to the legislature until late in March, had never emerged from the printers and consequently have not been generally available. The present bill is along general lines permitting the formation of the new State Department of Health on a broad foundation.

The question has been asked, why was not the vital statistics department put where it belongs, under the health department? The only answer is that the legislature in its wisdom voted earlier in the year not to do this very thing. And the answer to the question of why was not the milk inspection provided for? is that the majority of the legislators do not appear to wish what seems to us as desirable milk legislation and that so far, the farmers of the state are not able to see that it is for their interest to have the State Board of Health look after the milk production.

The bill is on the lines that the JOURNAL has consistently advocated and when a clause is added arranging for the protection of the present employers and the change of administration from the old form to the new on the appointment of a commissioner, it is hoped that the bill, as drafted, will pass practically without amendment.

Truly yours,

A. K. STONE, M.D.

THE ANTI-VACCINATION BILL. A CORRECTION.

FITCHBURG, JUNE 1, 1914.

Mr. Editor: In your editorial on the "Defeat of the Anti-Vaccination Bill" in your issue of May 28th, ult., you say, "Mr. Moore of Leominster and many other public spirited members of the House deserve the gratitude, etc." There is no Mr. Moore of Leominster in the House. The medical profession and all friends of good government in the 11th and 12th Districts will, I am sure, thank you if you will note the error and say it should read, "Mr. George F. Morse, Jr., Lancaster, Representative of the 11th District."

Mr. Morse was active in working to defeat this bill, and also on the floor of the House made a strong protest against its passage. Mr. Morse is a worthy son of the late Dr. George F. Morse of Clinton, a medical examiner and member of The Massachusetts Medical Society, a wise counsellor and cherished friend of mine while I was a resident of Lancaster, from 1870 to 1874.

Thanking you in advance for correcting this unintentional error, I am,

Very respectfully yours,

FREDERICK H. THOMPSON, M.D.

SOCIETY NOTICE.

AMERICAN CLIMATOLOGICAL ASSOCIATION. — The thirty-first annual meeting will be held at Atlantic City, N. J., June 19 and 20, 1914. President, James M. Anders, M.D., Philadelphia; secretary and treasurer, Guy Hinsdale, M.D., Hot Springs, Va. Members of the profession are cordially invited to attend the meetings of the Association.

RESIGNATIONS AND APPOINTMENTS.

TUFTS COLLEGE.—*Dr. Frederic M. Briggs* has resigned as secretary of the medical and dental faculties, and has been appointed professor of surgery and secretary emeritus. *Dr. Frank E. Haskins* has been appointed secretary to succeed Dr. Briggs on Sept. 1.

RHODE ISLAND BOARD OF HEALTH.—*Dr. Henry S. Bernstein*, director of the Bender Hygienic Laboratory at Albany, N. Y., has been appointed state pathologist and bacteriologist of Rhode Island.

RECENT DEATHS.

SIR FRANCIS HENRY LAKING, M.D., who died in London on May 21, was born in 1847. He studied at St. George's Hospital Medical School and the University of Heidelberg. He was consulting physician to the Victoria Hospital for Children and physician-in-ordinary and surgeon-apothecary to King George and the Prince of Wales. He was a member of the Royal Institute of Great Britain and Knight Commander of the Royal Victorian Order.

MR. STEPHEN TOWNSEND, who died on May 20 in London, was educated as a surgeon, and became a Fellow of the Royal College of Surgeons of England. He soon gave up the active practise of surgery, however, and became best known as a lecturer, actor, and author. His most familiar work is "A Leaf from a Hospital Day-book."

BOOKS AND PAMPHLETS RECEIVED.

Operative Surgery for Students and Practitioners. By John J. McGrath, M.D. F. A. Davis Company, 1913.

The Psycho-analytic Review. Published by the Journal of Nervous and Mental Disease Publishing Company. Vol. 1, No. 1, November, 1913.

The Uterine Myoma and Malignancy. By W. P. Manton, M.D. Reprint.

The Door is Open. By W. P. Manton, M.D. Reprint.

Bulletin of the Massachusetts Institute of Technology. Catalogue, December, 1913.

Report of the Surgeon-General, U. S. Army. 1913.

Transactions of the American Otological Society, Forty-sixth Annual Meeting. Vol. XIII, Part 1.

Medical and Sanitary Inspection of Schools. By S. W. Newmayer, A.B., M.D. Lea and Febiger. 1913.

Original Articles.

THE PRESENT STATUS OF PSYCHOANALYSIS.*

BY JAMES J. PUTNAM, M.D., BOSTON,

Professor of Diseases of the Nervous System, Emeritus, Harvard Medical School.

THERE are two main reasons why I am glad of the chance to speak tonight on the subject of the psychoanalytic movement, in which for the past four years I have had a share that, small though it has been, has meant more intense and more engrossing labor than I have ever spent on any previous task—a labor often involving much readjustment, sometimes far from pleasant but very satisfactory in most of its results.

In the first place, this movement represents a great boon to many sufferers from a series of extremely distressing and disabling maladies,—more distressing than any one is aware who has not watched the disastrous evidences of them, day by day and from close at hand.

To illustrate this point from my own relatively small experience, I will cite the following case-outlines, which indicate (so far as mere samples can do this), first, that mental disorders ordinarily classified as very serious can often be relieved in this way; next, that neither a bad family history nor long continuance of the symptoms are a necessary bar to improvement or substantial recovery. It goes without saying that this treatment, like all others, has its well-marked limitations, which it neither can nor should be expected to overpass. The persons to whom it appeals, whether as patients or physicians, will be mainly limited to those who are inclined and able to see that a large share of the troubles of this world have as their basis the doubleness of the mental life and the consequent misconceptions of individuals with regard to the influences by which they are being moved. A portion of these misconceptions is due to the fact that men fail to see, perhaps have never been trained to see, that we stand, not as separate individuals, with duties that end in the promotion of our own superficial interests, but as members of smaller and larger communities and groups, and eventually of ideal communities. The sense of isolation, doubt and terror, of jealousy, even of depression and despair, which are so prominent as causes of human misery, and especially of the misery of neurotic patients, would undoubtedly be far less if men were carried along by a sense of devotion to some great cause, some great religious sentiment, in which their longing for more exclusive, personal successes should be merged.

If this were the whole story, then the direction in which the remedy was to be sought would be clearly indicated, in theory at least. But, in fact, this is not the whole story, and the problems at stake cannot be wholly met by a completer recognition of social, or even religious obligations.

There is certainly another great element of difficulty at stake, which consists in the existence of schisms of the personality and self-misunderstandings, that have their root in subtle disorders of development which begin in infancy. These disorders are of such a sort that they cannot be classified as wholly due to an imperfect recognition of the unseen forces which we describe in terms of moral and social obligation. The persons whose development has been disturbed in this way to any considerable extent, are apt to find, at the time when they come up against the necessity of making moral choices, that their ability to do justice to their best qualities has been undermined by tendencies which have not until then been made obvious by definite results, and of which the nature and mode of origin are entirely hidden from the view.

Such persons find themselves saddled with desires, cravings, or habits which they seem under compulsion to obey, or from which they can escape only by the discovery of some subtle compromise which makes the apparent escape a delusive unreality. Of what benefit is it, for example, to escape from a self-indulgence of some infantile type, only to be left a person of overwhelming prejudice or narrow vision, or of blind and hostile pride?

Fortunately, even these compromises are often attended by a sense of distress which may lead the individual to attempt, with expert aid, to discover the true source and nature of his difficulty. It is in meeting this need that psychoanalysis plays an effective part.

A recent personal letter from Professor Freud, dealing with the theory of the treatment, concludes with this sentence: "The great ethical element in psychoanalytic work is truth, and again truth; and this should suffice for most people. Courage and truth are in what they are mostly deficient."

This proposition might well be taken as the motto of the psychoanalytic movement, for it is truth at which it aims. And the recognition of this principle should serve also as an answer to those who might be willing to see something of value in Freud's demonstration that it is possible, by means of his association method, to enable patients to see more deeply into their own histories and yet are unwilling to accept the results which psychoanalysis has thus far brought to light and have no patience with the details which are brought out.

Without these details, however, the principle would be of little worth, and the acceptance of the principle is often only a cover for an inner rejection of every attempt to apply this principle for the benefit of an individual patient.

* Read at a meeting of the Medical Section, Boston Medical Library, in conjunction with the Suffolk District Medical Society, April 1, 1914.

Finally, the fact cannot be too strongly emphasized that there is no necessary hostility between this mode of treatment and any genuine agency for good that social life or the ingenuity of any physician has to offer. On the contrary, in so far as it sets the patient free from the tyranny of his less good impulses, psychoanalysis should make him more susceptible to influences corresponding to the better elements of his nature.

CASE 1 is that of a gentleman of middle age, who had been suffering for about fifteen months from serious paranoid symptoms, accompanied with intense depression and a strongly marked suicidal tendency, on account of which it had been necessary to confine him, against his will, in a sanatorium, where he remained about a year. He had improved somewhat when I saw him, and it is not impossible that he would have recovered after a time without psychoanalytic aid. Nevertheless, considering that he was still deeply despondent and suicidal, so that the services of two male nurses were thought necessary, that under this treatment he improved steadily and fairly rapidly, and that he has had no recurrence in the three years that have elapsed since his recovery, the case seems worth recording, even at greater length than is here possible.

This patient had always been of a gentle disposition, highly refined, sensitive and self-depreciative, and had suffered from environmental conditions which received their tone from the temperament of the mother and grandmother, who, though high-minded, cultivated and refined, like himself, were out of touch with many of the more aggressive and practical interests of a boy's life.

It may be accepted as eminently probable that the qualities thus far mentioned first became developed as a result of reaction to positive emotional desires; but whether this is so or not, it is certain that these desires existed and acted as one of the strong influences of his whole life. He was unquestionably a person who suffered from the need of an outlet for feelings which he strove, without success, to sublimate, but in reality repressed. Any fancied sin against sexual purity (as a single, almost accidental, seminal emission at the age of about fourteen), or against the traditions by which he was surrounded, often gave rise to an agony of remorse. Yet his sexual excitability and his curiosity about sex topics were quite strong, and he was thus drawn continually in opposite directions, and became thereby irresolute and inclined to suspiciousness and depression.

This tendency to feel himself drawn in opposite directions was illustrated also very clearly in his relations to his mother. He was devotedly attached to her, but being fond of society in a wider sense he failed to find in her a complete outlet for his emotional life, and thus came to have a morbid sense that he was neglecting her for others, a double feeling that had a deep subconscious root. So matters went on until his mother's death. Some time previous to this he had been occupied in teaching in a boys' school, and had also been through several rather intense attachments which, however, had resulted in nothing except a series of friendships tinged with an unsatisfied desire for something more. The death of his mother seemed to let loose a number of conflicting tendencies, and led gradually to an emotional crisis which reached its culminating point about two months later. He then had a severe "Angst"[1] attack, after which a tendency to suspiciousness, which formed a part of his self-depreciatory habit of mind, became more and more intensified, and associated itself with gloomy forebodings. A specialist was called in, whose attitude and treatment only added fuel to these flames. The patient felt himself humiliated and crowded down, and took easily to the idea of a hostile conspiracy, as a species of relief. Removal to a sanatorium only made bad matters worse. The attendants treated him, as he believed and still believes, with considerable harshness and neglect, and very soon he found himself living in the midst of a fantasy world in which he played the victim's part with every one for his enemy. If a book was sent to him by a friend, he saw in it, both in general and in detail, only studied attempts to mock at his condition. To this end the writers had devoted their main efforts. Certain colors, and various other signs, seemed to him to be displayed to irritate and distress him, and false interpretations were placed by him on every act. Not only real persons, but the powers of the nether world were discovered to be in league against him. The devil's mark was traced on the avenue of the sanatorium, as a sort of bar beyond which he could not safely pass; and this element of his delusional state became so strong that even when fairly well on toward recovery he would exhibit, at least verbally, a degree of belief in this evil deity which seemed strangely at variance with his intelligence and cultivation.

At the time at which the treatment was begun, his physical health, which had previously been reduced, had become somewhat improved, but his delusions (only a small part of which I have here outlined) were still present in full force. The beneficial effect of the treatment soon became apparent. It was an immense relief to him to trace out, through the study of reminiscences and dreams, the mental influences which had brought him where he was, and to discover that it was possible to neutralize their effects.

It gradually became possible for him to utilize again his fine intellectual and temperamental traits in the interests of a wide life of friendship and social usefulness, and it is my belief that, understanding the situation as he now does, it would be almost impossible for him to suffer a serious relapse.

[1] The German word "Angst," as technically understood, covers a good deal more than can be indicated by any corresponding word in English. Its symptomatology is made up of both mental and physical elements of emotional excitement and distress which often reach a high point of severity.

CASE 2 is that of a lady who had been treated by me without success before my interest in this movement began, and later successfully by this method. Her symptoms, which were of several years' duration, consisted of compulsive and torturing doubts, the extension of which was without limit. It seemed to her impossible to disprove the possibility, dreadful to contemplate, that plants and trees were capable of suffering like men, and this was but a sample of a distrust on her part of the power to form judgments of any sort or even to feel that she had the right to be sure of her own identity and name. This doubting habit had not prevented her from working, it is true, but it had made her exceedingly unhappy, and had given her a sense of isolation at contrast with her naturally sociable and friendly tendencies.

The analysis gradually made it clear to her that her present paradoxical doubts were only covers for a series of uncertainties about old problems of personal conduct, and moral responsibility for definite acts and tendencies of childhood and adolescence of which she was ashamed. It was in the conflicts centering on these early tendencies—that had originated in a craving for personal self-indulgences and personal affection, at variance, as she thought, with a set of ethical standard which she longed to consider genuine—that the habit of doubt became established. For, blame and criticize herself as she might she could not shake off the fact that she had strongly emotional traits, and, until she became able to secure a rational comprehension of her own nature and her ethical obligations, she had no recourse but to make her doubts themselves, and her false reasoning about them, the servants of the emotional longings. She had become accustomed, and with reason, to regard herself as immature, but could not make head against this immaturity until she came to see in just what respect the estimate was a just one.

In cases of this sort an element of peculiar difficulty for the treatment is often furnished by the fact that the reasoning power itself becomes sophisticated, and is prostituted, as it were, to the keeping alive of the tormenting but fascinating doubts.

This was so in her case. Gradually, however, improvement set in, and for a long time the patient has been so well that except for short periods, during times of especial stress, she has been mistress of her thoughts.

CASE 3 is that of a lady still under my care, whose history may be condensed as follows:

Up to the age of about twenty she was ordinarily well balanced, a fine scholar at school and college, finding perhaps too strong an attraction in her literary work with its appeal to her esthetic sense. She was intensely, perhaps too intensely, devoted to her mother, who was for a number of years an invalid. Yet she insists that this relationship was in no way narrowing or unwholesome, but rather of a broadening tendency.

Later analysis brought out several facts about this early period, which, trifling as they had appeared, have become of material significance in indicating the existence of conflicting trends in her temperament. Had her mother lived, or had she been able to work out a life on lines other than those that she was forced to follow, all might have gone well. But while she was in college her mother died, and she was then called upon to face situations which were not in harmony with instinctive desires that had become stronger, subconsciously, than she knew, to the exclusion of traits of which she stood in need and could not spare. Then inner conflicts began to show themselves, which became especially intensified after her marriage (in itself a very happy one), and forced upon her a series of obligations which she felt herself unfitted to assume, and under conditions peculiarly hard and uncongenial.

Sick, thwarted, and disappointed, she began to react against herself and her environment with an intensity difficult to express adequately. Persons whom she had every cause to love became objects of horror and detestation, and these feelings were poured copiously upon herself as well. Home-making became an impossibility, her despondency bitter and severe, and the desire to end her miseries by her own act a longing scarcely to be resisted.

In spite of the call of obvious duties such as she had never previously disregarded, and in the face of an obviously rational outcome apparently within easy grasp, the inner obstacles in the way of a successful attainment of her best wishes seemed almost insurmountable. Moods of violence lay always close beneath the surface; and though better moods were also near at hand, yet the better moments were fleeting, and for the most part she kept being overwhelmed as if by waves of destructiveness, or drawn out beyond her depths by a strong undertow of despair. It was only after many months of almost daily treatments that anything like stability seemed to come within her reach. But at present a better outcome seems to be in sight, and the main trend is gradually toward a better state. And the result has been due to the equally gradual defining of the removable portions of the difficulty in terms of the undesirable trends of character and temperament which the patient is learning to discard in the interests of a better sort of progress.

CASE 4 is that of a lady, an artist by profession, and of highly neurotic stock, who for some ten years had been tormented by morbid fears which made it painful, if not impossible, for her to go down town, or to places of entertainment. This sense of fear, which was indescribable but prostrating, and for which no obvious cause could be assigned, was gradually traced to longings and cravings which had their origin deeply in her temperament, and which she had been unable to face out, because never fully aware of their meaning or existence. She had had treatment from excellent physicians, but without avail. In the course of a few months, however, she became substantially relieved, so that she could go everywhere with but slight traces of discomfort, and could finally take a foreign trip. I have heard from her at intervals, and in very gratifying terms.

CASE 5. Another case which has interested me greatly is that of a young man, gentle in demeanor, rather small in stature, a chronic masturbator, suffering from timidity and morbid consciousness of himself, who since earliest childhood, as if either

seeking a compensation from these tendencies to a sense of insufficiency, or with the primary love of self-assertion which every infant feels,[1] has indulged in grotesque day-dreams of heroism and domination. In these day-dreams, which came to his memory gradually, during a moderately long treatment, he felt himself a king, or even tyrant, able, like Nero, to gratify fanciful ideas of cruelty. His dreams, like his experiences, have illustrated the concealed motives of his life,—to override others and to seek protection for himself. In a recent dream, of obvious tendency, he found himself at first indentified with the pilot of a newly-built steamship of high power, which he called "Novelty," and in which he was ploughing his way rapidly and successfully through a winding channel into an open sea. Then the scene changed, and he was (like Phaeton aspiring to drive the wagon of the Sun) the easy master of a four-hourse sleigh, in which again he was making his way at full speed toward an open and unknown but unfeared land that lay before him.

In thinking of this case and others of like sort, the image has come frequently to my mind of a pair of Siamese twins, each invisible to the other and endowed with opposite characteristics. How could this patient expect to make his better ideas of progress and usefulness avail, so long as they were harnessed to this unrecognized desire for power and domination? The difficulty became even more apparent when, after recognizing the significance of the situation, he admitted that this half hidden love for power, although alien to his more conscious personality, was something from which he could hardly bear the thought of parting. Fortunately he has learned to see, not only in his day-dreams, but also in his depressions, his numerous fears, his doubts, and even in his trains of over-ingenious reasoning through which he seeks to justify his false positions, the evidences of personal self-indulgence, the mental equivalents of his masturbation.

In all these respects he is making excellent progress toward character development, and thus recovery.

I have made no attempt to show in detail the mode in which, in these cases, the basis of the later symptoms was laid down in infancy and childhood. It would be impossible to do this satisfactorily without entering at length into the personal histories of each patient, as well as into the discussion of Freud's whole doctrine of infantile and childhood psychology, and his theory of the part played by the accentuation, through arrest, of one or another specific phase of infantile development.

It is enough, for present purposes, to point out that such patients fail to live happily and to work out their best birthrights, by no means always because life offers them so little in the way of health, opportunity, inheritance, or fine traditions, but also because of influences of more or less accidental and theoretically avoidable sort, emphasized in infancy and because of early longings and cravings, which perhaps social traditions, perhaps conscience, could not justify.

In Case 5 the egocentric tendencies of the patient were fostered through the injudicious influence of a nurse who for a long time played toward him the mother's part, though by no means in the best sense. Unfortunately, the sense of supremacy thus early emphasized did not stimulate him to take a really leading part in practical life, even in childhood, so that it was only through idle day-dreams and postponement of daily tasks that his theory of leadership could be kept alive. All the greater was the sense of downfall when actual trials proved this theory to be untenable.

As regards the value of the method used in treatment, I desire to emphasize the point that there is no necessary hostility whatever between this means of securing benefit and those employed by men who prefer to stimulate their patients to march forward, through work, loyalty, and wholesome living. It is, indeed, difficult for me to conceive why any one should consider the interests of medical progress served by the suggestion that this hostility does exist, while it implies on the other hand a most unfortunate narrowness of view with regard to the varying needs of psychoneurotic patients. Every one whose experience is at all large has seen an abundance of cases where influences which ought to have turned out favorably, if neurological treatment of the old style was practically or theoretically sufficient, have turned out, in fact, anything but successful, because no one had sufficiently recognized the terrible handicap which internal conflicts may create. Of what use to urge such sufferers to toil, pale and panting, toward the summit of their Mount of Difficulty, when they must drag along an unseen ball and chain which deeper insight might remove, leaving them able not alone to help themselves but to show a wider sympathy for their neighbors? The case which comes frequently to my mind in illustration of this sentiment is that of a clergyman, a man of the finest character and highest principles, who was obliged to live as a voluntary exile in a hospital for the insane because he was carried away by the obsession that he would kill some member of his family, to which he was, in fact, devotedly attached. The case was of a sort which is now known to be almost invariably modifiable under favorable conditions, and usually curable under the best conditions, through the psychoanalytic method; and although in this case the best was doubtless done that could be done, yet the time will come when it will be considered a disgrace that such a patient should remain, year after year, with the proper remedy for his malady unsought. The fear of killing, in such cases, represents the persistence of a fantasy of childhood, clothed with emotions which are usually referable to

[1] Ferenczi has pointed out that the infant, by virtue of the fact that he is the centre of attention, and, through a series of specific signals, can secure the accomplishment of his will, is liable to acquire a sense of all-powerfulness which may easily become intensified and persistent. Internationaler Zeitschrift für Aertzliche Psychoanalyse, Jahrg. ii, Heft 2.

conditions prevailing at that period of the patient's life and removable later through discovery of their origin.

In the next place, even the very principles underlying this movement have been dreadfully misunderstood, and in order that they may be correctly understood they should be studied carefully and repeatedly.

I shall use the remainder of my time in discussing certain of these points about which misunderstanding chiefly reigns yet should not reign, and will lead off with a few remarks about the central figure of the movement, Professor Sigmund Freud, whom—let me say—I regard as a personal friend, and have learned to respect as a man of superior cultivation and even genius.

I have learned to see in the modes of investigation adopted by this remarkable man, and by those who have followed in his path, the signs of intellectual honesty of a high order. There is room, no doubt, for considerable difference of opinion with regard to the interpretation of the symbolisms met with in dreams, around which controversy has so fiercely raged. But it should be borne in mind that these interpretations of a given symbol, as offered by any given psychoanalyst, are usually based on large numbers of observations by himself or others, through which the meaning suggested has seemed justified. Interpretations so based acquire the value of tentative, partial definitions, offered, of course, for the acceptance or rejection of those who are willing to take into account the conditions which led to the framing of them.

It should be remembered that Freud was, to all intents and purposes, a pioneer explorer in a new territory, and that he felt himself under obligation to report everything which he found there, at the risk of the loss of his own self-respect if he should fail, through carelessness or timidity, to do so. I say "new territory," for although perhaps none of the principles which Freud announced (such as the principle of repression or that of forgetfulness as an evidence of repression, or of the significance of the several stages of the infantile life for the characteristics of the adult, or of the importance of the sexual emotions) were wholly new, yet it was he who first gave to these principles accurate form and color, organs of locomotion, and an individual virile life; and it was that endowment that caused this great movement to command respect, on the one hand, and to evoke criticism, on the other.

People sometimes speak of Freud as if he had been the first one to speak freely of the sexual life, but in so doing they overlook the extensive publications of such men as Krafft-Ebing, Moll, Havelock Ellis, Janet, and many more, which, important though they are, have mainly slept on the shelves where they were deposited, unknown or shunned save by a few more curious or bolder readers. It was Freud that first breathed vital energy into this neglected topic, and forced its recognition by demonstrating its practical importance. One should not overlook the fact that the somewhat patronizing statements to the effect that Freud and his followers "have gone too far" in this or that direction, or have "misled" many persons to entertain false doctrines, have often been made by men who even now have never trodden the path broken by him through this wilderness, or who might live a thousand years without giving us the splendid gift of Freud's discoveries—a gift which, to be appreciated, should be looked at in terms of its best possibilities, its best animus.

There has been a great deal of misunderstanding also on the subject of Freud's attitude with reference to the significance of the sexual life in the causation of hysteria, and the psychoneuroses of other sorts. It is a great mistake to assume that in their analyses of a patient's case psychoanalysts see before them nothing but this special phantom. In the first place, it is emphasized by every writer that as a partial cause for every psychoneurosis, a predisposition exists, which it is impossible to define in exact terms but about which one can say that it implies an excitability of the emotional life, and hence of this great sex-emotion with the rest and predominantly with relation to the rest. This is a predominance which the sex-emotions may be said to share with the instinct to assert one's existence, in the sense of Schopenhauer's will to live or Nietzsche's will for power. But even these instincts may often be best described in terms of personal relationships, and therefore if one wishes (for reasons of practical classification) in sex terms. Next, it should be recognized that the objective point of every psychoanalysis is the placing at the disposal of the patient's conscious awareness, of everything which his own intuitions feel to be significant. Nothing is to be excluded which he can reveal, whether as regards the history of his environment in childhood and later, or his personal ambitions, or his religious views, or his opinions upon any other subject. More has never been maintained than the fact, testified to, or rather asserted, by the patient's own memory and power of inference, that amongst the turmoil of emotions which form the basis of his hidden complexes, the sex emotions invariably occupy an important place.

With psychoneurotic patients this particular passion comes preëminently into play, for the simple reason that it is not only one of the strongest by which men are moved, but the one most strongly repressed, and that it is thus placed on a vantage ground for special mischief.

For the sake of making clearer Freud's conception of the sexual I give a very free translation of one of the latest of his carefully drawn statements with regard to this point, again begging those who would pursue the inquiry further to read the fifth chapter of Dr. Pfister's[1] book.

[1] Oscar Pfister: Pedagogium, Band I: Die Psychoanalytische Methode.

"It is well known that psychoanalysts have been criticized for extending their conception of what is to be understood by the word sexual, far beyond the usual limits. The fact that they have done this is true; whether it is a matter for criticism is another question.

"The conception of 'sexual' as now defined by psychoanalysts is wider than the popular conception in both directions, and the reasons for this widening are best stated in genetic terms. We include in the sexual life the whole range of emotions which had the primitive stirrings of the sexual function as their main root, even when the emotions which were derived from these primitive stirrings are no longer directed toward what at first seemed to be their goal, or have even become directed toward a new goal which would ordinarily be classified as not sexual at all.

"Reasoning in this way, we prefer to use the word 'psychosexual' rather than 'sexual,' in order to make it clear that we neither overlook nor underrate the mental factor in the sexual life.

"In other words, we now use the word 'sexuality' in a sense equivalent to that of the German word *lieben.*"

In view of this definition and in recognition of what "love" stands for in normal life, can one wonder that the sex-emotions should play the prominent part that is ascribed to them in the causation of the psychoneuroses?

Another very important consideration for fair-minded persons to realize and remember is that when the term "sexual" is used by psychoanalysts with reference to some experience or symbol, it is by no means necessarily meant to imply that the grossest connotation of this word is present in the patient's mind. An important principle here comes into play. One justly classifies a series of phenomena by the most prominent and typical of its members, and if one is on the watch for elements of especial significance, of especial danger, for example, then one classifies with special reference to that point. "De potiori designatio fit," or, in other words, there are occasions on which to lay a hand, no matter if gently, on a man's arm is to commit assault and battery.

Another expression of this principle, and one which appeals strongly to me, would be to say that we can judge best of acts, as well as of men, by looking at their tendency or motive power, or animus; and this is something which is by no means always seen at first glance.

Let us suppose, for example (what must, from the evolutionary standpoint, be the case), that an unbroken line connects the sensuous with the spiritual and in terms of this situation let us consider the meaning of some given act. Let us suppose that one man kills another. If the animus or motive of the first man is in the line of sensuousness, or brutality, we call his act a murder. If it is in the line of the highest interests of the community we call it patriotism.

The question is whether the main trend of such a man's emotion, which in both cases takes in, theoretically, all that the whole line stands for, is more toward the spiritual or more toward the sensuous aspect of his nature.

To a great extent the problem before the nervous invalid is the same with that which every living man is forced to meet:

We come into the world with infinite possibilities ahead of us in the way of moral and intellectual development. Why do most of us fail so signally to realize these possibilities? Surely, in part, because to realize our best possibilities would imply a thorough utilization of powers of disinterestedness and rationality, of which all of us possess, indeed, the germ, but which we can employ only at the cost of setting aside the temptation to follow the broader and easier paths marked out by pleasure, passion, and self-interest.

The path of disinterestedness and reason is one that mankind has learned only comparatively recently, and, so, imperfectly to tread; the broad and easy path has been trodden by countless generations of beings from which we derive our life.

The conflicts here involved are old ones and have been called by many names, as that of the carnal, the natural, and the animal against the spiritual.

Adam and Eve, preferring knowledge, even with the chance of sin, to ignorance and static content, fought through this conflict in the garden, as Hercules trained himself to do, even in his cradle; and it is noteworthy that in both cases the serpent, symbol alike of sense-temptation and wisdom, played a prominent part.

In such exigencies as these, the child, ignorant of his danger, often endeavors to avoid the necessity of taking a definite stand by adopting a self-deceiving device, which is all the more effective because utilized almost wholly without conscious awareness on his part. The child, namely, instinctively learns that he can reject any given form of self-indulgence, so far as its original shape is concerned, and yet preserve its essence by encouraging its attachment to some otherwise indifferent and allowable conscious process. I am now defining a principle of general psychological significance, and not dealing with its application to any particular form of symptoms. But examples can be furnished by every one's experience, and are given on a large scale by the history of ascetism.

To combat this tendency to self-deceit only thorough-going methods will suffice. One has to learn to ticket, as with a red tag, the beginnings of evil. It is of little use to upbraid one's self, for our acknowledgments of fault and frailty are sometimes the very means by which we keep alive the essence of the fault and frailty.

I am free to admit that the psychoanalyst assumes a responsibility when he disturbs any equilibrium at which another fellow-being has

arrived, even such an equilibrium as his nervous symptoms secure to him. But this is true not of the psychoanalyst alone, but of the minister and of the educator, who, like the psychoanalyst, though perhaps in a less trenchant way, are continually endeavoring to bring about a new equilibrium better than the last. I assert only that psychoanalysis has its place and meets certain needs, in these difficult situations, which are not otherwise to be met.

Psychoanalysis helps the patient who has been driven to follow blindly an inferior vision of his destiny in which gratification or some subtle substitute for gratification plays so large a part, to strengthen the slender thread of his rational and spiritual life, and to see that his massive longings and personal affections, that hark back even to infancy, ought to be regarded not solely as something of value in and for themselves, but rather as bridges to something better.

SOME PERSONAL RESULTS IN PSYCHOANALYSIS, AND THE FUTURE OF PSYCHOTHERAPY.*

BY L. PIERCE CLARK, M.D., NEW YORK.

ON the invitation of your chairman, I shall undertake to make a few remarks upon the use of psychoanalysis in some of my own cases, and sketch in a manner what I think will be the future of psychotherapy. In a measure I know you will pardon me if I am somewhat personal at the beginning of my short paper.

Soon ofter graduation I began the study of nervous diseases because I was ashamed to admit during my first week in a general hospital training that I did not know peripheral neuritis from locomotor ataxia; the various forms of sclerosis of the cord meant nothing to me. After I had studied the old museum pieces of spinal cord and brain diseases in the incurable wards on Blackwell's Island, I was forcibly impressed with the very hopelessness of curing or bettering such advanced disorders of the nervous system. In an effort to get nearer to the beginnings of nervous disease, and especially brain disorders, I entered the Insane service on Ward's Island. In my mind I carried over to this service the idea that inasmuch as all the spinal cord and brain diseases I had so far seen had a gross pathology, the various insanities probably had their gross or microscopic lesion if one were able to approach these disorders with a sufficiently careful technique. Just at that time the refinements of sectioning and staining brain tissue were on their way, so I served an apprenticeship in this quest in Dr. Prudden's laboratory, working with Dr. Van Gieson. After a short study of the clinical and pathological material of the Asylum, I saw that some mental disorders, such as the arteriosclerotic dementias and general paresis, did have a more or less distinct pathology which was demonstrable to the naked eye or under the microscope, but that there were a host of other insanities with which one could do nothing in making clear their pathology neither could these mental disorders be classified satisfactorily (this was before the days of the Kraepelinian school) in consequence, no definite idea of prognosis was possible, and the result was that the treatment for all these insanities was practically the same. After several years' study of the convulsive disorders at the Craig Colony for Epileptics, and continued study in the clinics abroad, it steadily dawned upon my rather rigid and materialistic mind that out of the sum-total of nervous affections the special physician was called upon to treat, the majority of them were functional and had their origin for the most part in those persons who possessed illy organized physical and mental habits. The greater number of such nervous invalids had a peculiar type of personality which differed a good deal in different persons, but on the whole a certain defect of the same was always to be found and reckoned with in any rational diagnosis and treatment. I then began to realize for the first time that the large group of psychoneurotics and even those presenting milder types of the insanities needed in a great measure to be handled along psychologic lines; I saw I must cease thinking of these diseases in the strict terms of a nerve cell perversion and look more sharply yet simply into just what sort of human beings with which one really had to deal. From paling into a splendid martyrdom of laboratory research for the cause and treatment of these functional disorders, I found I most needed to gain more understanding of the different ways ordinary everyday mortals reacted to the various vicissitudes of life, more especially when they had this neuropathic constitution and personality. Like many another chastened special worker in this field, I saw I had greatest need of pencil, paper, a quiet room, lots of patience and a certain amount of tact, and that in future I could well afford to spend less time in an especially equipped physiologic and psychologic laboratory to find out what really ailed nervous people. The idea, you will percieve, was all very human and an outgrowth of reasserting common sense. Please do not misunderstand; I do not depreciate the employment of all the best means of physical diagnosis and the use of the most advanced drug therapies and physical therapeutics that may be brought forward.

After this somewhat random and personal introduction, I shall undertake to give you some results I have had in the study and treatment of the psychoneuroses as shown in a few selected individual cases. The method or study and

* Read before the Medical Section, Boston Medical Library, in conjunction with the Suffolk District Medical Society, Boston, April 1, 1914.

treatment in all which I shall attempt to give were treated by psychoanalysis, the details of the use of which I trust you are all familiar with from the admirable teachings of Dr. Putnam.

I shall give only the merest outline of the cases, any one of which in detail would outrun the time allotted to this short paper. I take it for granted that your individual experience with the use of various types of physical therapeutics such as baths, massage, work, etc., are sufficiently well known to be devoid of interest at this time.

The first two cases that opened my eyes to the great importance of an intensive analysis of the inner life, were referred to me by two of your Boston physicians.

The first case was that of a young unmarried girl. She had recently graduated from college at 21. She suffered from hysterical convulsions and from other convulsive seizures that were thought to be genuine epilepsy. These disorders had existed for several years and had defied all the usual plans of treatment for either disease. Inasmuch as I could not prove to my own satisfaction that she had ever really had epileptic seizures in which tongue-biting and incontinence of urine occurred, and in the absence of certain physical and mental stigma of epilepsy which one might expect in such cases, I determined to make the one disease of hysteria go as far as it would—a bit of chiding, but wise advice, I learned to accept from my studies with Hughlings Jackson. The girl was an extraordinarily clever girl and practically analyzed her own case for me, at least so far as the conscious field of her life was concerned. Then by a series of intensive studies of her dream life we succeeded in unearthing a love of self-inflicted pain which served as a sexual satisfaction, called masochistic pleasure, and which had been a conscious practice in youthful days, but which had gradually relegated itself entirely to the realm of the unconscious life, and provoked the hysteric attacks, which were really phantom representations of the sexual act. After we had gotten all these facts unearthed and made plain, all the different types of fits ceased. The girl soon took her proper place in the intellectual world and commanded a salary of $3,000 a year, in a position which she resigned last year to work for no salary, plus love, having married a poor but very able physician. I never obtained so much cheap credit for performing a miraculous cure before or since. The clever girl really analyzed herself, and took me along: I followed and saw the wonder of it all. The whole experience was as convincing of the value of psychoanalysis, at least in such cases, as when I saw the diphtheritic membrane peel off a child's throat after the administration of antitoxin.

The second case, which, however, was not a consecutive one in my experience with psychoanalysis, was that of a married woman of 56 living in New York, referred to me by another Boston physician. She had periodic depressions of such an intense character as to be classed as mild attacks of manic-depressive insanity. There were great depression, loss of sleep and appetite, indecision, neurasthenic pains, slow thought, considerations of self-destruction, etc. The attacks had occurred at least twice a year since her marriage at 24. Her continued illness had engrossed the whole family and wrapped them in gloom truly pitiful to contemplate. Thorough analysis disclosed her periodic depression to be really a compulsion neurosis at heart, in which there were certain phobias of death and fear that there was no God and no immortality; all these ideas by dream analysis proved that this woman had a very fixed infantile attachment to the aunt (her mother died soon after her birth) and that the panics, fears and depressions were really substituted mechanisms from an unconscious desire to die and be united with her aunt who had died. It is unnecessary to say that her marriage was a non-sexual one, and efforts to adapt to new relations brought out the symptoms. Even going to the country and coming back to town or making any new adaptations in life always brought on her depressions. After three months' treatment she was so much better that she discontinued treatment of her own initiative. She has never had a depressed day since the analysis. The treatment was finished five years ago. This case is cited for special reasons; two practical points are worthy of note. The analysis was, of course, not as complete as I thought it should be, yet it was evidently thorough enough to bring about a practical cure; the other point is that psychoanalysis was undertaken in a rather "set" woman of 56, an age often thought too advanced for such a plan of treatment. It all goes to prove that one must not follow any hard and fast rules in an age-limit in psychoanalysis nor in stating just how long the analysis must be made. I have had another equally successful case of relatively the same sort in a woman 60 years of age.

I am impressed the more carefully we study the one time periodic neurasthenias and the same type which has later been designated manic-depressive or cyclothymia, that many such cases which on superficial examination seem to belong to the above types really belong to the compulsion neuroses with obsessive ideas. This point is of more than academic interest inasmuch as at the present time no line of therapy has been able to prevent or greatly retard the recurrence of subsequent attacks in such individuals. The case above cited is the more remarkable as more time intervenes. I have others like the one just cited that promise as well in final outcome, but only time will prove this point.

For a number of years I have been interested to see what treatment can be employed for incipient cases of dementia praecox,—whether they can be conserved from going on to the deterioration requiring asylum care. From some half-dozen such cases studied and treated two may be briefly cited.

The first, a young, unmarried man of 29 years of age, who had been twice in sanitaria for nervous disease for periods of several months each. The mental disorder had been in existence six years when I first saw him. He was a typical case of dementia precox with mannerisms, stereotypy and a

delusion that God was killing him by casting his thoughts upon him, etc. A rather complete analysis showed that he had a firm mother attachment. He began masturbation at seven years of age and continued it off and on thereafter. He had a marked musical ability and at fourteen tried to stop masturbating by throwing all his energies into his music, but at this time his mother, who had kept him company in musical education until that age, was obliged to discontinue her practice with him. Immediately the patient recommenced his habit of masturbation. He then joined the church as a defense against this practice. The music and church work combined were effective for a time. He felt best and was free from torture of sexual thoughts when he played music, but some five years ago he played secular music at a church fair held in a church, and since that time until I saw him two years ago he played no more music; again he commenced masturbation, became listless, inattentive, slovenly, and developed his complete series of a precox symptom. Analysis showed that music meant all the sexual satisfaction he had prior to the intensive practice of music. When he played secular music in a church he thought he had committed the sin of polluting his own and in fact all religion, and therefore God had sought to punish him in the manner outlined in his delusion. He was sufficiently accessible to bring many of these ideas into a semblance of rational adjustment. His physical and mental habits were readjusted and his main avenue of strongest contact with the outside world of reality through his music was carefully opened again. He is now doing fair work in a theatre orchestra. He has lost his peculiarity of manner and conduct and to a great extent seems to have been conserved from a useless existence.

If such a man had been taken early after his great conflict under which he broke entirely, it would seem that much more might have been done for him. I believe it is popularly held by many alienists that dementia praecox is an organic insanity, but while that popular belief is being substantiated, why should we not handle many of the accessible cases somewhat upon the lines detailed?

The next case had an even more promising outcome; a young, unmarried girl of 19 who had been adjudged a case of paranoid dementia precox. She had delusions that she was being hypnotized, that her thoughts were being read by many people, and later that God had given her direct power to save the world. The final dream analysis showed that the *hypnosis* was a wish desire of a sexual character for a certain man for whom she had an unrequited love, and that God was the father complex sublimated. Her own father had rather seriously admonished her to go out in the world and earn her own living as all the other members of her family had done. The divine power idea had been a dream at first and she continued it in the waking state as a fixed belief. Her physical and social surroundings at home were very bad; these were all changed, and gradually the analysis opened her outlook to the real life about her. An aunt took her under her protective care and the young girl is now busy and happy as a designer in a millinery establishment and is pursuing some language studies in a neighboring school. She states that the former delusions are like a half-forgotten bad dream.

I think these two cases of dementia praecox go to show that we physicians, during the several months before many of these cases go to asylum commitment have a distinct duty to perform. Inasmuch as the average asylum life of a dementia praecox is about fifteen to seventeen years, ought we not to try to conserve these cases if possible by extra mural treatment?

Furthermore, the more we study cases of craziness, which the benign or recoverable psychoses have been called, the more we will find that the crazy ideas and apparently meaningless jargon of such patients have a real meaning when carefully analyzed, and if we will but take the pains to piece these sayings and acts together the more will we see that they really intimately concern the real difficulties with which our patients have unsuccessfully coped. The mental content I believe in time will be found to give us real clews to many of the conflicts with which our patients unsuccessfully contend.

A number of us are studying the innate nature and mental treatment of the tics. We have already found that such disorders as mental torticollis and the facial tics are really the motor expressions of certain types of mental conflicts which require some physical acts. When such individuals are fully freed of their tic disorder by a detailed analysis, the result is surprisingly good. When we realize how stubborn to treatment *tic convulsif* has proven in the past we should hasten to welcome any rational plan of therapy that promises any measure of permanent success. It is ironically amusing that the facts concerning tics which we are but just now working out in detail Charcot long ago elaborated in general terms. We now see the master's original precept and the detailed facts of today are united in a complete whole. During the past two years I have treated several cases of tics upon the foregoing grounds and the results so far have been excellent.

One of my first cases of tics studied as a psychoneurosis was that of a man 28 years old, unmarried, an expert bookkeeper, who suffered one of the severest grades of left spasmodic torticollis I have ever seen. At first it seemed that he were none other than one of the so-called professional tics. With my consent, the surgeon by whom I was first called in to see the young man, did a full resection of the spinal accessory and the cervical nerves of the left side. This treatment was of no avail. The case was then turned over to me to make the best of a bad job. That which seemed at first like a just punishment to me to further handle the case, turned in the end to be a reward. I employed the reeducative methods, massage, electricity and all the usual correctional nerve remedies. I then undertook a minute inquiry into the exact manner in which the tic developed. The first analysis showed that the patient had worked under great physical and mental stress at cross-ledger accounts; this, in conjunction with a severe psychic shock, seemed

sufficient to cause the tic, but further inquiry was pursued. The next study of the case showed that since school days and earlier he had had a very persistent habit of stroking the left side of his head; this habit was consciously broken off a few weeks before the tic developed. When under great mental stress he felt that he wanted to do this previously automatic act of stroking, but he suppressed the inclination, and while he was finally successful in controlling the movements of the hand, the head wobbled and finally broke away from control in the torticollis, as shown in the disease from which he sought relief. In the next study we determined to unearth the origin of the habit movement. This finally proved to date from a caressing, petting act of the mother in rocking him to sleep in his nursery days. It was further shown in dream analysis and other methods of approach to the infantile life that our ticeur was surcharged with many doubts and fears and states of obsessive thinking since he was a child, and that back of all these compulsive thoughts and desires he had conflicting doubts which resulted in indecision and vascillation. A three months' analysis enabled us to clear the situation. He has no torticollis today and has been well for over a year.

Another case was that of an unmarried woman of 36, with a professional tic torticollis to the right. All the older forms of psychotherapy failed in other competent hands and in my own. Psychoanalysis revealed an incompletely repressed sexual attachment to the father, which broke out in the tic when she undertook onerous and worrying tasks in a business office, the manager of which was the source of an unrequited love on her part. A three months' treatment has reduced the spasm, taken out all the secondary defense acts to control the tic and she is comparatively well, at least as long as the call for new adaptations in her home and her new work is not too severe. I may say that in both the foregoing cases extraordinary changes in character and ability to do better work have incidentally been brought about by the treatment, although psychoanalysis was undertaken primarily for the tic disorder.

The third case I shall mention briefly; it is the most surprising one in its rapid improvement. The young man had the greatest number of different tics and habit movements I have ever seen. In the heydey of the tic disorder last fall when I first saw him, he had 13 different habit movements and tics, which were as follows:—

(1) Biting of finger nails following finger sucking. (2) Grimacing tic, involving the whole face. (3) A genuflexion tic. (4) Sighing tic. (5) Laryngeal, clicking tic. (6) Autoecholalia (repetition of some or all of the words in a declamatory statement) which finally ended in (7) an exclamatory tic, "Huh! huh."; a so-called grunting tic. (8) Tousling the forelock of hair, which ended in (9) the finger tic of tousling imaginary hair. (10) Picking the finger nails, which succeeded the cessation of biting the nails. (11) Picking the face, which resulted in a profuse suppurative acne over the entire face. (12) The ablution tic, wringing the hands and washing the face. (13) Panics and fears that he was to faint, lose his mind, meet with an accident and be killed, or that he was to die.

To make a long case analysis short, they were all resolved back to their genetic origin, and in two months' treatment they all disappeared except the autoecholalia, the sighing tics and the panics. The autoecholalia is a repetition of certain words in sentences which the patient himself has just uttered, and has the following explanation: Inasmuch as the patient has always had doubt and uncertainty of doing and saying the proper thing (obsessive neurosis), he contracted the habit of repeating aloud the essentials of the sentence, the headlines of the idea as it were, and in this manner he relieved and quieted the doubt and feelings of inadequacy. Much the same was shown later in his underscoring and repeating certain phrases and even ideas in his writing. In the process of inhibiting this disagreeable repeating of words, he first stopped repeating whole sentences, then single words, and now the phenomenon amounts to but a beginning of speech, a sort of exclamatory speech, and the former intellectual act has been almost inhibited, but there still remains the semivoluntary muscular larynx and diaphragm contractions. Here we have the complete conversion of a psychic process into a physical act or tic. It has completely lost its former mental meaning. This tic has now practically disappeared. The sighing tic went with the panics. The boy had the panics and fears since he was 11 years of age, or since the father's death. He had such a homosexual father attachment that he attempted to die by holding his breath, going without sleeping or eating, etc., which were all childish attempts at suicide. The fears and panics came on first in the dreams three or four days after the father's death. In such the father came back, and it seemed as though he had never been ill; then he came in dreams as though he were ill but recovering; then he returned, was ill, and died; then he returned, was ill, died, and the patient strove to follow him, with all the feelings of the panics and fears. All the dreams ended in a nightmare, not understood until the full drama of the final act in the dream was brought into the conscious life. Then the father dreams ceased. He then dreamed rarely of the father, but had panics and fears which were in conscious symptoms what the pursuits of the father image in death-dreams were. A free association of death brought out an exact description of his panics and fears. All difficult or new adaptations brought on the panics, such as going away from home, meeting strangers, or going to little social gatherings. The most extraordinary result has been brought about in this case from a three months' analysis—the tics are gone, the panics and fears flowing out of a deeper trend in his life are nearly absent. The young man is at work half the day and attends an occupation school the other half. He is neat, cheerful, orderly and, in the words of his former despairing sister, he is a "reformed and agreeable young man."

I think there can be no doubt that all ticeurs have a constitutional makeup and certain peculiar types of mental conflicts that place them with psychoneuroses of the compulsion type, and such neurotics ought to be treated by psychoanalysis when possible. The first case I mentioned had his disorder five years, the second two years, while the third had most of his tics from earliest childhood and his true obsessive thinking from his eleventh year, which goes to show the length of time the tic has existed has

little to do with the prognosis. The main issue for real successful treatment is a sincere desire on the part of the ticeur to rid himself of the disorder coupled with his willingness to follow the psychoanalyst.

In speaking more directly to the text allotted to me by your chairman,—the future of psychotherapy,—I am aware that I am stepping from the firm ground of proven facts to that of prophecy, the unsubstantial footing of which you shall be the judge. In the beginning I shall say that I consider there is but one real thorough-going plan of psychotherapy, and that is psychoanalysis. All the other schemes of hypnosis, suggestion, persuasion, re-education, etc., are but incomplete half-way stations in the handling of the psychoneuroses. I have used all the latter for years before I undertook psychoanalysis, and I have discarded them all for the latter. I would not have you believe that I hold that the psychoneurotic cannot get well of his ailment by any of the host of other plans of psychotherapy; indeed, one of the most miserable of psychoneuroties, a personal friend of mine, has been relieved of his disorder for many years by Christian Science.

Psychotherapy, and therefore psychoanalysis, in its fullest sense, is a jealous goddess and demands much of one who would follow its practice. It will not only always demand extraordinary amounts of time and patience from one who uses it, but I believe many who will undertake the work will prove totally unqualified to practice it, and in consequence we must be prepared to see the method fail and many reproaches heaped upon its misapplication and the misapplier. One of its very regrettable features is that it takes the psychoanalyst very far afield from the ordinary practice of medicine, and especially from all the phases of organic neurology. Indeed, it would seem in some instances to be almost a separate profession from that of medicine as we ordinarily see it practiced. In some instances our best analysts are not physicians at all. I believe, however, every analyst should have a careful and experienced medical and neurological training. A definite medical sense is absolutely necessary in dealing with mental and nervous disease. Many of you would think it unnecessary for me to speak of this, but I wish to remind you that a large part of the work in the care and treatment of the feeble-minded still rests in the hands of psychologists or in lay hands untrained in either psychology or medicine. I hesitate to give you what I think the full measure of a man and physician should be to undertake psychoanalysis, for you will see I do not consider it to be a method which even the average well-trained neurologist may follow at option. There is no reason, however, why all of us should not know about its principles and its use. I think none of us need feel that this plan of treatment is in any real danger of getting too remote from real service to legitimate medicine, simply because we hear that some of its votaries are setting folk-lore, mythology and many phases of psychology and metaphysics on a firm foundation and meaning. It will be remembered the enthusiastic workers in neurology at its inception happily went far afield and cleared many an obscure issue in kindred specialties of medicine. Most of us can remember at the advent of bacteriology one had need but to scrape one's tongue before breakfast and become famous by describing a new germ before dinner.

Now about neurotics: It now seems possible that in a few years sufficient careful studies of the more common forms of the psychoneuroses will have been made so that we may lay down some rather specific and general rules in parental and school education for the proper bringing up of neurotic children so the neuroses may be less frequent, or at least much easier handled when the psychoneuroses do occur. Then, too, the accumulated facts will surely point the way to wiser and more tolerant customs of society toward the unfortunate neurotic, when we learn that certain kinds of physical and mental training are important for the proper balance of the emotional life and that all sexual matters will have their proper place in a cultural education. Many of these points have already been so carefully and wisely set forth by Dr. Putnam that I shall but refer you to his masterly writings upon this subject.

Finally, in closing, I believe we should all hold ourselves open for the reception of evidence of the inner mechanisms of the psychoneuroses and the insanities, for in this latter respect we at last have much hope that even paranoia, the depressives and dementia precox in the exact manner of their mental development will not long remain in mystery. I do not mean we shall know their physical causes by these intense analyses, but we shall gain an insight into their precise mechanisms and find how they break down into the several psychoneuroses and psychoses.

MEXICAN NOTES.—Report from Mazathan, Mex., on June 1 states that smallpox is epidemic among the constitutionalist garrison of Culiacan, the capital of Sinaloa. On June 1 the United States Army completed its first month's occupation of Vera Cruz. During this period over 7000 soldiers and marines have been ashore without a single death among their number from disease. On June 5 there were 78 sick among the soldiers at Vera Cruz, a percentage of 2.23, and 101 sick and injured among the marines, a percentage of 3.3. There are several cases of malaria aboard the despatch boat *Dolphin* off Tampico. The army medical corps now consists of 445 members, with 89 in the active reserve corps and 60 in the dental corps.

INDICATIONS FOR OPERATION ON THE SEMINAL VESICLES.*

BY J. BENTLEY SQUIER, M.D., NEW YORK,

Professor of Genito-Urinary Surgery, New York Post-Graduate Medical School.

MY early experience with operative work upon the seminal vesicles was limited to excision of the organs when they had become diseased by tuberculosis. In 1911 I began removing vesicle, vas and testicle, in those cases presenting evidence of tuberculous epididymitis with spermatic cord involvement. It seemed to me poor surgical judgment to leave an infected vas and vesicle, when excising a tubercular deposit in the epididymis, as it would be to leave behind a known tuberculous ureter when removing a tuberculous kidney.

Since this phase of the symposium is to be elucidated by Dr. Young, I make mention of it merely to explain that it was through this work that I learned how comparatively simple it was to reach the seminal vesicles by perineal exposure.

I believe one of the main reasons why surgery of these organs has remained undeveloped for so long a period, has been largely due to the current opinion that the vesicles were of such difficult surgical access. One American surgeon has for the past ten years devoted a large amount of his time to surgery of these organs and has contributed much to the literature. He has apparently not aroused the interest of the profession proportionately to the importance of the subject. Needless to say I refer to the work of Dr. Eugene Fuller of New York.

While some may not be as enthusiastic over the possibilities of drainage of the seminal vesicles, nevertheless, when the history of the surgery of these organs is complete, his will be the glory of one who has blazed the trail. Our apathy in this direction is responsible for this admission which I must make, namely, that probably no surgeon in this room can, at the present stage of our knowledge, definitely outline just what are all the indications for operation upon the seminal vesicles, or how it is possible in many cases of systemic toxemias or joint lesions conclusively to prove disease of the vesicles to be the causative factor.

We know that certain portions of the body by reason of histologic formation and anatomic situation are prone to chronic infections.

These infections are characterized by focalization, extreme chronicity with acute exacerbations, and protean systemic manifestations, due to a constant discharge of infectious emboli into the circulation. The interrelationship of endocarditis and infected tonsils; urethritis and gonorrheal rheumatism, "sore throat" and nephritis has been conclusively proved. These examples have attracted more investigation because the interrelationship was more obvious than with other forms of chronic sepsis. The idea has become dominant that many forms of arthritis can be explained as end results of focal infection; however, the determination of these points of infection and their correlation with the systemic signs, has been a matter of difficulty. Nevertheless, it can scarcely be doubted that many of the arthritides have their origin in occult focal infections. We believe that chronic infections of the seminal vesicles are an undoubted source of some of the deforming arthritides whether they are of the atrophic or hypertrophic type. Infections within the vesicles do not lend themselves to a natural drainage by reason of their relation and peculiar anatomy. It is questionable if an infection of the vesicle is ever rendered sterile by natural drainage through the ejaculatory duct into the urethra. On the contrary it would seem that resolution takes place by an encapsulating process with scar tissue formation.

The amount of cicatrix and perivesiculitis found at operation in most of our cases would presuppose that the infection had been "walled off" by scar tissue, rather than resolution having taken place with sterilization of the infectious foci. Such a condition continuing, a chronic sepsis of low virulence may occur, a bacteriemia which Adami designates as a subinfection. This chronic sepsis finally produces a break, so to speak, in the immunity of the individual and then there appear, after a variable time, systemic manifestations. The occurrence of systemic manifestations is by no means entirely confined to the joints but may affect other tissues—endocardium—renal epithelium, etc. The reason the joints are so frequently involved would seem to rest upon a number of factors. First, the synovial membrane is a tissue not particularly resistant to infectious processes. Secondly, the synovial fluid is lymphocytic rather than leucocytic and does not offer a marked phagocytic power. Thirdly, the almost constant irritation of joint surfaces incident to locomotion, etc. A clinical fact not to be lost sight of, is that disability in a joint very easily makes its presence known, whereas the same is not true of an infection of the heart or kidney, where it may exist for years without making its presence known.

Chronic infection within the vesicles by the time systemic manifestations develop, has undoubtedly become a mixed infection, with pyogenic bacteria as the predominant type. Cultures from the vesicles at this period are uniformly negative for gonococci but reveal an almost constant growth of pyogenic bacteria. Rosenow has demonstrated that the cultural characteristics and morphology of bacteria may be modified or even undergo mutations by an alter-

* Read as part of a Symposium, "The Genito-Urinary Tract as a Factor in the Production of Chronic Toxemias and Joint Lesions," before the New England Branch of the American Urological Association. Boston Medical Library, Boston, February 17, 1914.

ation of the environment; and upon the development of different strain streptococci and pneumococci from a single strain streptococcus or pneumococcus, together with the study of the lesions produced by these different strains, a reasonable explanation may be deduced for chronic rheumatism and rheumatoid conditions.

If we follow the reasoning of Adami, relative to subinfection, and the researches of Rosenow in the production of experimental myositis in rabbits, and apply it to our seminal vesicle work, we find an easy explanation for many of the phenomena encountered. For example, let us suppose that the gonococcus, having been liberated from its usual habitat—the genito-urinary tract, into the general circulation undergoes metamorphoses and emerges as a different form of coccus. Upon focalization, the lesion produced will necessarily conform to the type usually caused by that group of bacteria which it now resembles. Let us believe that in many instances the metamorphosed gonococcus appears as a streptococcus, or that the lesion produced in the vesicle by the gonococcus has attracted to it other bacteria as a suitable resting place for multiplication, and the various systemic manifestations of gonorrhea are explained.

The particular grade of attenuation of the bacterium will determine the severity of the lesion.

The milder grades will localize themselves in the muscle capillaries, multiply but for a short period and disappear by lysis, the symptoms produced being only muscular aches and pains. With reference to these infectious emboli, "it appears that as soon as the bacteria set up a reaction, whether by their mere mechanical presence, or by endothelial phagocytosis of some of their number and liberation of their endotoxins, that reaction is adequate to destroy the rest of the bacteria, and this with relatively very slight accumulation of wandering cells. But the liberated and diffused endotoxins are sufficiently powerful to destroy the more highly differentiated cells in the immediate neighborhood, and following this destruction there is, in favorable cases regeneration or in unfavorable cases, a replacement and even a productive fibrosis" (Adami). Thus is explained the nature of the more severe cases of joint disease where the lesions found are of the nature of a connective tissue hyperplasia.

The rarity of endocarditis following gonorrhea in adults, and the possibility of endocarditis in children in certain instances being primarily due to a gonorrheal infection, is also made clear. In adults the heart valves have become nonvascular, the arterioles present in childhood in the proximal two-thirds of the cusps having become obliterated.

The work of Opie on experimental production of cirrhosis of the liver, by action of B. Coli, that of Gaskell, of Libman and Baehr on the form of nephritis produced by streptococcal embolism in the capillaries of the glomeruli, are strong arguments for recognition of this condition of subinfection as the underlying cause. The chief characteristics of the condition of subinfection are: it is recurrent, a lesion occurring from it is not suddenly produced but takes place gradually as the "summation of a succession of minute insults to the tissues, sometimes occurring within a few days or weeks but often extending over years" (Adami). Those of you who are familiar with bacteriologic advances may consider that I am wandering from my subject,—the indication for operation on the seminal vesicles. Nevertheless it has seemed to me advisable to incorporate the foregoing in this paper, if only to strengthen the argument that there are indications for operating upon the vesicles.

In selecting cases for operation, and by operation I am referring only to surgical drainage of the vesicles, I have grouped them into three rather general classifications—pus, pain and rheumatism.

Pus Groups.—(a) Those in whom suppuration is the predominant feature. This will include definite abscess formation within or around the vesicles. The surgical indication in such cases is so obvious that but mention is made of it. However there is a border line group, namely those who develop an acute seminal vesiculitis and prostatitis during the course of a specific urethritis which does not terminate in localized abscess, who I am inclined to believe would fare better if subjected at once to operation rather than be treated by expectant measures.

These are the cases in whom rest in bed, hot rectal irrigations, etc., cause a subsidence of the acute symptoms and we compliment ourselves that we have "aborted" a prostatic abscess, only to have a long tedious case of chronic seminal vesiculitis to deal with. I have not had sufficient experience as yet with operating upon this type of case to warrant advocating it as a routine procedure, but when we reflect that from the anatomic arrangement of the tube-systems of the vesicles, the chances for early resolution and spontaneous cure are only four per cent., it seems that such a procedure might be justified, especially if we find that drainage of the vesicles produces a permanent cure and not merely a transient amelioration of symptoms.

(b) Cases of recurrent epididymitis following acute urethritis and vesiculitis, the operative indication being vesical drainage combined with epididymotomy.

(c) The chronic type of seminal vesiculitis, often rather difficult to diagnosticate as the symptoms are not so well pronounced as in the acute form.

The history of urethritis, or stricture; discomfort in the perineum, increased upon difficult defecation; tenesmus; frequent erections without sexual stimulus and frequent nocturnal emissions, often bloody in character; and the presence of pus in the semen. These cases have

to be decided upon their individual merits according to the effect the symptoms are having upon the patient's general health, since it is perfectly possible for a patient to suffer from the above without greatly impairing his general health or sexual activity.

Pain.—The group in which persistent perineal pain has seemed a sufficient indication for operation have presented some interesting features.

Three patients, with histories of more or less constant perineal ache associated with recurrent urethral discharge have been found at operation to be suffering from calculi of the seminal vesicles. In but one was this possibility considered before operation. This patient gave a history of "colique spermatique." The colic occurred during coitus and the pain experienced was excruciating. The acuteness of the pain subsided and a persistent soreness and ache in the perineum remained. The calculi in all these cases were found to be composed of phosphate and carbonate of lime and were true calculi.

I am under the impression that calculus formation in the seminal vesicles is more frequent than has been formerly considered. Given a chronically inflamed vesicle with a partial occlusion of its outlet, ideal conditions are indeed present for their production, and doubtless further collated operative data will prove this contention.

Rheumatism.—The indication for operation in cases where joint lesions are present is definite; namely, if the focal infection can be proved to be the seminal vesicles,—drain them—but here is the difficulty of the whole question.

Llewellys F. Barker in his original article, "Differentiation of the Diseases Included Under Chronic Arthritis" (*American Journal of Medical Sciences*, Jan., 1914), states as follows: "We should also when using the term 'infectious' keep clearly in mind the difference between (a) an infection in a joint-system itself, and (b) an infection somewhere in the organism as a whole, with secondary non-infectious changes (toxic, nutritive, trophic) in a joint-system. I emphasize this point because of the great importance, in the chronic arthropathies, of minute foci of infection distant from the joints and of their removal as a therapeutic measure. Chronic inflammations of the paranasal sinuses (including the antrum of Highmore), chronic tonsillitis, chronic otitis media, pyorrhea alveolaris, alveolar abscess, chronic bronchitis, chronic ulcerative enteritis, chronic appendicitis, cholecystitis, chronic pyelitis, chronic cystitis, chronic urethritis, spermatocystitis and prostatitis, chronic salpingitis and chronic endometritis may be mentioned among the many possible foci whence influences injurious to the joint-system may emanate, and this without prejudice as to whether these influences are (1) metastatic infection, (2) toxic, (3) neurotrophic, or (4) noxious in all other ways.

It may, therefore, be really appreciated that before a definite conclusion can be arrived at as to the influence a diseased vesicle may exert upon the production of a chronic arthropathy in any given case, a very great amount of differential exclusion must be seriously considered.

My experience with drainage of the vesicles in patients suffering from infectious arthropathies has been limited to the acute or subacute varieties. In every case a recent gonorrhea has been present so that the relationship between disease of the vesicles and the joint seemed definite. In every case immediate cessation or amelioration of the joint symptoms has resulted. I am firmly convinced that drainage of the seminal vesicles offers more for the cure of typical cases of gonorrheal rheumatism than any other means as yet suggested.

CANCER OF THE UTERUS.

THE POSSIBILITIES OF CURE BY THE RADICAL ABDOMINAL OPERATION. CERTAIN ORIGINAL METHODS OF OPERATING. INCLUDING AN ANALYSIS OF 367 CASES AT THE MASSACHUSETTS GENERAL HOSPITAL.

BY FARRAR COBB, M.D., BOSTON,

Visiting Surgeon to the Massachusetts General Hospital.

(*Concluded from page* 868.)

THE INCISION.

The satisfactory completion of this operation with wide removal of the parametrium and upper portion of the vagina necessitates a generous exposure of the pelvic field. The incision should be in the median line and should go down to the symphysis and always must be carried above the umbilicus. I have in most cases adopted a modification of Gibson's method in operating for low ureteral stone; namely, cutting across the anterior sheath of the recti just above the symphysis. This alone gives appreciably more room. In obese cases or difficult cases I do not hesitate to partially divide the tendinous insertions of the recti muscles. It is a relatively easy matter to repair the recti by mattress stitches at the end of the operation.

MANAGEMENT OF THE URETERS.

The dissection and handling of the ureters, freeing them from the parametrial tissue, is the most important technical part of this operation. The object is to have them free so that they can be lifted up and out of the pelvis, and at the same time preserve their own blood supply and thus avoid subsequent necrosis and fistulae formation. The method introduced by Howard Kelly and still, I believe, practised at Johns Hopkins, of inserting ureteral bougies before operation as aids in finding and dissecting the ureters, I only mention to condemn. It is time-consuming and unnecessary not only, but, on the other hand, it is a distinctly dangerous procedure because the bougies act as rigid splints and prevent displacement of the ureters and at the same time exert a counter resistance and pressure and so contribute to necrosis. It is seldom difficult to locate the ureters if one begins to look for them high up near the bifurcation of the iliac arteries. In obese patients, and cases which are complicated by old pelvic infection with adhesions, the finding and isolating of the ureters may be most difficult.

I have perfected an original method of using tapes to retract and lift the ureters out of the way, protecting the ureteral blood vessels by rolling over a fold of the peritoneum. After the ovarian artery has been tied and the broad ligament opened up, the peritoneum being divided above the bifurcation of the iliac arteries, the ureter is exposed lying on the inner and posterior peritoneal flap of the broad ligament. The internal iliac artery is then exposed and ligated with chromic catgut, after which the posterior peritoneal layer of the broad ligament is incised below the ureter midway between the bifurcation of the iliac arteries and the uterus, parallel with the ureter and about half or three-quarters of an inch away from it, and through this slit tapes one-half an inch wide, wet with sterile salt solution, are passed, surrounding the ureter. Traction on these tapes serve to roll a cuff of peritoneum about the ureter, this cuff can be more definitely demarked by vertical incisions. I have found that with this method I could make fairly strong traction on the ureters without damaging their blood supply.

In Figures 2 and 3 I have tried to show in a diagrammatic way the method of making the broad ligament cut and applying the tapes. I have found the method to be of great value in dissecting the vesical end of the ureter, and also, more especially, when dividing the parametrium and cutting across the vagina. In my more recent operations I have not hesitated to use additional tapes under the ureter itself close to the bladder in the final stage of the operation using gentle traction. I have never had an ureteral fistula, although in many cases I have made fairly strong traction on the ureters. It should be stated that the ureter should be traumatized as little as possible. If its blood vessels are injured even a little, necrosis and fistula formation can occur. In 500 of Wertheim's cases ureteral fistulae occurred thirty-two times, and he says that in twelve of these cases it occurred where separation had been easy and there was no reason to suspect injury. In Wertheim's experience the ureter is rarely if ever involved in cancer, although it may be

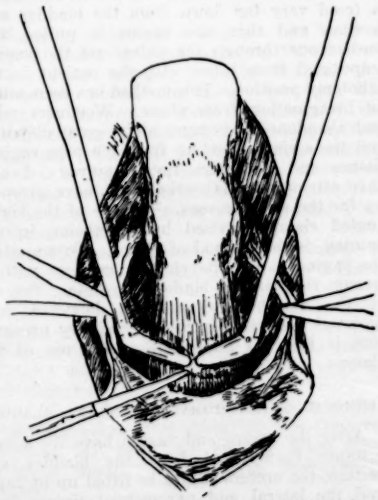

FIG. 3.—Showing method of using tapes in elevating and retracting the ureters.

surrounded and compressed by malignant disease.

PREVENTION OF INFECTION AND IMPLANATION METASTASIS FROM THE GROWTH AND THE VAGINA.

The chief cause of death in this operation is septic peritonitis; the second most frequent cause is shock. Next to the dissection of the ureters I consider the most important part of the technique the method to prevent septic or cancerous infection. The source of infection, obviously being the ulcerated infiltrated growth of the cervix, and the presence of discharges and organisms from the growth in the vagina in spite of all attempts at sterilization. One of my fatalities was due to a rapid septic peritonitis. Two of my recurrences have been rapid metastasis in the pelvis, presumably implantation metastasis. There are only two methods to consider from the point of view of avoiding infection. One, devised by Werder of Pittsburg in this country, is technically too difficult and dangerous to be considered as a routine procedure. In this method the vagina is freed very far down from the bladder and rectum, and then the uterus is pulled and pushed out through the vulva and the vagina amputated from below with the patient in the lithotomy position. This method has been called an invagination from above. Wertheim tried and abandoned it because of its great difficulty and the serious bleeding from the para-vaginal tissues and the extra time required. I also have attempted this method, but have given it up for the same reasons. The use of the right-angled clamps devised by Wertheim, in my opinion, is the method of choice. To amputate the vagina I use the electric cautery with a strong, right-angled blade if possible. The use of the curette and cautery, however, and thorough dissection in the preliminary preparation is fully as important as the use of the clamps.

REMOVAL OF THE PARAMETRIUM AND GLANDS.

After the uterus and vagina have for a long distance been freed from the bladder and rectum, the ureters should be lifted up by tapes and the lateral and parametrial tissues from above the internal os well down the sides of the vagina should be removed with scissors close to the pelvic wall. It is in this removal that one is likely to have great trouble with obstinate venous bleeding deep down in the pelvic hole. After the operation has to all intents and purposes been completed, I have not infrequently had to spend half an hour in patient effort to stop this deep venous bleeding. I have never had a case in which I could not do so, although others have reported deaths from uncontrollable hemorrhage in this region. The use of small right-angled hemostats is very important in clamping off the parametrium. Figures 4 and 5 illustrate the extensive removal of the parametrium and the vagina. This specimen is from the same case as the chart in Figure 1.

FIG. 4.—Specimen from case whose chart is shown in Fig. 1. Note wide removal of parametrium and upper portion of vagina.

FIG. 5.—From same case as Fig. 4.

In cancer of the cervix the first glands involved are the iliac, those glands lying between the internal and external iliac arteries. The

glands next are the obturator and last the sacral and inguinal. Cases in which the sacral and inguinal glands are involved are beyond doubt absolutely unfavorable. It is impossible to remove all the glands. Wertheim's decision that only glands that are palpably enlarged should be removed is now accepted by most operators. Enlarged glands are not necessarily cancerous by any means. In over half of my cases in which the iliac glands were distinctly enlarged and removed, the pathologist reported, after a careful serial examination, no cancer, but enlargement due to hyperplasia; that is to say, enlargement was due to the arrest of septic material from the ulcerating growth.

A thorough survey early in the operation for glandular conditions is necessary, and it should be understood that to do this properly the peritoneum must be split and the great vessels laid bare, for in no other way can one determine accurately by sight and palpation whether the glands are pathological. If numerous enlarged nodes are felt, especially in the sacral chain, a radical operation is inadvisable and the operator should content himself with a simple hysterectomy. If the iliac and obturator groups are moderately involved, the glands should be removed as the last thing in the radical operation. Theoretically, they should be removed at the first of the operation, or in continuity with the parametrium, but it is impossible in this operation to establish a lymph block as in operations in the breast and neck. In many cases the glands can be removed easily, but in cases where they are adherent to the iliac veins they will be removed with difficulty and risk.

CONTROL OF HEMORRHAGE.

In my last paper on cancer of the uterus, I said it was problematical how much ligation of the internal iliac arteries would interfere with pelvic nutrition and especially influence post-operative cystitis, and in cases where a large dissection had been made, would increase the chance of sepsis and necrotic sloughing. Since that writing I have ligated the internal iliac arteries in the majority of my cases. Instead of adopting the former method, that of Wertheim, of tearing through the tissues along the pelvic wall and lifting up the uterine arteries on the finger right after tying the ovarians, I have carefully exposed the ureters on the inner layers of the broad ligaments, and then deliberately tied the arteries on both sides. While, because of the free anastomosis, the ligating of the iliacs does not control the hemorrhage from the uterines absolutely, it enables a much clearer dissection, an easier freeing of the bladder and a deliberate securing of the uterines when they are cut across, also diminishes arterial bleeding deep down when the vagina and rectum are freed. I am convinced from my cases that this procedure does not in any way cause bladder complications or necrosis; cases in which I have done this have done fully as well as those in which I have not done so. This procedure is especially valuable in cases of obesity and in which the room in the pelvis is small.

DRAINAGE.

Drainage through the vagina with long strips of iodoform gauze, the peritoneal surfaces being sutured over so as to form a floor above the gauze is, in many of the cases, all that is necessary. The gauze strips should be started on the fifth day and removed an inch or two daily until all has been withdrawn. In a few cases where there is reason to suspect unusual infection of the peritoneum, where the bowel has been injured or the bladder resected, abdominal drainage also is wise, and in my recent cases, where I had reason to fear unusual accumulation of blood below the peritoneal floor about the vaginal drain because of obstinate venous oozing, I have also used the abdominal drain at the lower angle of the abdominal wound for a few days and have been surprised to see the amount of serous drainage which this has taken care of.

The after treatment is simple. The head of the bed should be elevated a foot for the first week and salt solution given by rectum every five or six hours. In cases where one has reason to suspect unusual infection of the peritoneum, continuous salt solution by rectum is advised. The use of the inlying catheter for three or four days is a routine followed in my cases, and this, with the use of urotropin will in most cases prevent any unusual post-operative cystitis.

Of my 23 radical hysterectomies for cancer of the cervix at the hospital four died as a result of the operation, one on the second day of peritonitis, a very difficult case in a very obese woman; one in twelve hours of shock; one on the tenth day, cause of death not made out at autopsy; one case died in the fifth week of iliac thrombo-phlebitis.

Five of my first six cases have lived from five to thirteen years after operation free from recurrence. All have been seen or heard from within a month. Very briefly, they are as follows:

Elizabeth C., W. S., Vol. 369, p. 120, Jan. 4, 1901, age 35 years. Symptoms,—pain and flowing for six months. Had been curetted by a doctor. Cervical growth size of half a dollar, marked thickening and induration in left broad ligament. Iliac glands on both sides removed.

Pathological Report. Squamous cell carcinoma of the cervix; glands not malignant.

Madeline V., Hospital No. 134507, S. S., Vol. 83, p. 287, Oct. 16, 1903. Age, 48 years. Symptoms,—for five months excessive flowing and pain. Extensive cauliflower growth of cervix, uterus movable.

No thickening in the broad ligaments. No glands removed.

Pathological Report. Squamous cell cancer of the cervix.

JANE S., Hospital, No. 140882. S. S., Vol. 107, p. 143, Jan. 14, 1905. Age, 60 years. Symptoms,—for two to three years bloody discharge, some pain, loss of weight and strength. Cervix hard and indurated, several deep ulcerations, uterus movable, broad ligaments not thickened. One enlarged gland in the left iliac region removed.

Pathological Report. Squamous cell cancer of the cervix; gland non-malignant.

ETHEL H., Hospital No. 150169, S. S., Vol. 137, p. 23, Nov. 6, 1906. Age, 27 years. For five months symptoms, flowing and pain. Had been curetted by a doctor. Badly eroded cervix with free hemorrhage. On examination broad ligaments not indurated. Bladder torn in operation. Iliac glands on left enlarged and removed.

Pathological Report. Squamous cell carcinoma of the cervix. Glands not malignant.

ROSE S. E. S., Vol. 620, p. 105, Hospital No. 159940, Aug. 24, 1908. Age, 35 years. For fourteen months symptoms, constant flowing and foul discharge. Cervix hard, nodular and excavated. Uterus not freely movable. Induration in both broad ligaments. No glands removed.

Pathological Report. Squamous cell cancer of the cervix.

To have cured five out of six cases is, obviously, largely a matter of luck. I would not be surprised if my last six cases died of recurrence, but I am greatly encouraged to go on with the radical operation as I have been doing it.

TABULATED ANALYSIS OF THE CASES AT THE MASSACHUSETTS GENERAL HOSPITAL FROM 1900 TO 1913 INCLUSIVE.

Total number of cases.....367

Clinical Department.

I. PRIMARY SARCOMA OF STOMACH.

II. PYLORIC STENOSIS OF THE NEW BORN.

III. CONGENITAL INTESTINAL OBSTRUCTION IN A NEW-BORN BABY. REPORT OF CASES.

By A. R. Kimpton, M.D., Boston.

PRIMARY SARCOMA OF STOMACH.

The following case is of interest, not only because of the comparative rarity of gastric sarcoma, but because of the fact that the patient was known to have had an abdominal tumor for years. Yet at the time of operation she was not anemic or emaciated, nor did she have any gastric symptoms other than indigestion (apparently hyperacidity).

The abdominal tumor was supposed to have been an ovarian cyst, with a long pedicle, that would at times become partially twisted and cause some disturbance. The patient was seen by myself for the first time on the morning of the operation, preparations having been made by another surgeon. He being ill that day, I was asked to operate, as the patient was prepared and did not wish to wait. The abdomen was opened, expecting to remove an ovarian cyst.

The following history was obtained after the operation:—

Physician's wife, 30 years of age. Father and mother living and well. Remainder of family well. As a small girl from three to five years of age, she was subject to severe attacks of pain in epigastrium and other regions of the abdomen. These attacks lasted until relieved by drugs, and were followed by great weakness lasting three or four days. The physicians called were unable to assign any cause. On one occasion ether was administered to relieve the patient. Menses began at eleven years of age and she had much pain at these times up to seventeen years of age. As a young girl she was troubled a great deal with "sour stomach," and at the time of her marriage was in the habit of taking a large amount of sodium bicarbonate, which she gradually ceased to do, and for eighteen months had no trouble at all with her stomach.

Patient states that she discovered the tumor when eleven years old, but never spoke of it until after marriage, four years ago. It has troubled her more or less by occasionally being sore and painful. Within the last two years the tumor has increased in size gradually and has given more discomfort in every way. The digestive upsets have been more frequent, at times necessitating only liquid diet, but the patient never vomited.

With the exception of these attacks of "indigestion" the patient considered herself in perfect health and certainly appeared perfectly well.

The tumor was movable and the probable diagnosis was an ovarian cyst. The one thing against it was that it could not be brought into the pelvis, although it could be brought as low as the umbilicus. Many of her symptoms could have been laid to the dragging and pulling of almost any abdominal tumor.

Operation, December 29, 1913. Abdomen opened through an incision made below the umbilicus, expecting to find an ovarian cyst. Pelvic contents were found to be normal and a movable mass was found in the upper abdomen, which could be pulled down as far as the umbilicus. There were no adhesions. Extending the incision to a little above the umbilicus, it was found that a tumor of the stomach was to be dealt with. There was not only the large tumor, but many smaller ones. A choice between a simple exploratory operation and a very extensive resection had to be made. The patient was in excellent condition. The tumor mass was local so far as could be made out, although there were palpable somewhat enlarged lumbar nodes. A partial resection of the stomach was decided upon. It was necessary to resect so low on the duodenum that the stump was turned in with considerable difficulty. The stomach, likewise, had to be resected high in order to take in all of the tumor. A conservative estimate of the amount of stomach removed would be one-half. The resection was done with an actual cautery. The lines of suture were reinforced with omentum so far as possible. The remaining portion of the stomach was so small that a posterior gastro-enterostomy was accomplished with some difficulty. There were some enlarged nodes along the greater curvature of the stomach which were removed with the tumor. A cigarette drain was left in the upper abdomen and the abdomen closed in layers. The patient went back to bed in excellent condition with a pulse of 110. The drain was removed on the second day and was not replaced. The convalescence was uneventful throughout.

The patient left the hospital on the twenty-first day, having lost only three pounds in weight, and since then has been in perfect health. A bismuth x-ray was taken six weeks after the operation by Dr. George, as shown by the illustration. The specimen (see illustration), was examined by Dr. William F. Whitney, and his report is as follows:

Microscopic Examination showed a solid growth of irregularly rounded cells separated into small lobules by connective tissue bundles, and with but little intercellular substance between the cells. In many of the cells the nuclei were eccentric. Here and there were mitotic figures and double nuclei were occasionally seen.

Diagnosis. Round cell sarcoma.

The small tumors were examined as well as the larger.

As the drawing shows, the tumors varied in size, some being pedunculated, were largely at the pyloric end of the stomach and did not cause any stenosis. The largest tumor was partly broken down. This is the usual condition found in the round-celled type, which is the most common type of gastric sarcoma. Dr. Whitney agrees that, although the pathological report was not that of myosarcoma it would seem fair to assume, from the long duration, that the growth was originally a myoma.

PYLORIC STENOSIS OF THE NEW BORN.

This case is reported for the purpose of showing a picture of the condition, not that it adds anything unusual. The baby, sick for five days with vomiting, was seen then by Dr. John Mitchell, who made the diagnosis.

Boy, three weeks old. First baby. Normal delivery and apparently a normal baby. Nursed well for two weeks, gaining over eight ounces the first week, and about the same the second week. Began vomiting the first day of the third week, and has been vomiting now for six days. Vomits all the milk taken, either at once or soon after nursing.

Examination. Well developed child and apparently still in fair condition. Rectal examination reveals nothing abnormal. Abdomen not distended. Palpation of abdomen shows a tumor in the region of the pylorus. This was easily palpable by placing the fingers low on the abdomen and gently sliding the fingers under the edge of the liver.

Before both parents could be reached and preparations for operation made the baby died. The pathologic report by Dr. Whitney was the usual type of hypertrophic stenosis. The photograph shows well the tumor and its customary extension along the greater curvature of the stomach.

It would seem that these cases had best be considered as emergencies, and possibly cases seen late might be saved by doing a jejunostomy through a left rectus incision. This could be done very rapidly and practically without general anesthesia.

CONGENITAL INTESTINAL OBSTRUCTION IN A NEW-BORN BABY.

Case was seen with Dr. A. L. Brown of Winchester:—

Italian baby girl four days old, born without medical attendance. Had had no movement since birth. On the second day parents noticed that baby's abdomen was distended, but did not call a physician until the fourth day, when the child began to vomit. Baby had been to the breast a few times.

Examination showed a well developed child with a much distended abdomen. Rectal examination showed a patent rectum as high as could be reached, and from the rectum an inspissated, putty-like material was being discharged. There was no meconium, but a large amount of this putty-like substance had been passed.

It was decided to quickly make an artificial anus in the hope that more could be done later should the child be so fortunate as to live. This was done, the abdomen being opened through a left rectus incision. A very definite volvulus reduced itself as some loops of small intestine came into the wound, but no gas or meconium was passed. There was some free, blood-stained, fluid in the abdominal cavity. No large intestine could be found, therefore a fistula was made in the most dilated loop of small intestine handy. Through this fistula a large amount of meconium was passed. No search was made for the cause of obstruction. This took a very few moments and the baby's condition was little worse after the operation, but the child died a few hours later.

The post-mortem findings were as follows: The intestinal tract from the stomach to within about three inches of the ileo-cecal valve was normal. Here there was complete obstruction. Meconium had never passed this point. The obstruction was caused by a firm band, coming from the right side of the pelvis and grasping the ileum in such a way as to cause a complete twist. The large intestine was a mere patent band. The material it contained arose from its own secretions.

The fact that the baby did not vomit until the fourth day, and that enough of this inspissated material had passed to empty the large intestine, should have led to the conclusion that the obstruction was low in the small intestine.

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

THE VACCINE TREATMENT OF SKIN DISEASES.—RESEARCH STUDIES IN PSORIASIS.—ARTIFICIAL ERUPTIONS FROM CRUDE COAL TAR.—PEMPHIGUS TREATED BY QUININE INJECTIONS.—ALOPECIA ATROPHICANS.—MEDICAL COSMETICS OF THE SKIN.

THE VACCINE TREATMENT OF SKIN DISEASES.[1]

At the meeting of the 17th International Congress of Medicine, held in London in August, 1913, Dr. T. C. Gilchrist, in the dermatological section, opened a general discussion on the above subject. He said in his paper that vaccine therapy had now reached, especially in America, a stage somewhat similar to that of x-ray therapy during the first two years of its application, when collectively it probably did more harm than good. Many people are now so prejudiced against x-ray treatment that they refuse to have anything to do with it, and so it is getting to be with vaccine treatment. He compares the treatment by commercial mixed vaccines, containing often as many as nine or 10 kinds of organisms, with the old "shot-gun" prescriptions, when it was hoped that the remedy would hit something.

Gilchrist records his experience of vaccine treatment in about 800 cases of skin disease during a period of six years. He asserts that he has had brilliant results, moderate successes, and many failures, probably about in equal proportions. He considers that the only true method is by the use of autogenous vaccines. Vaccines are of the greatest value in chronic or subacute, and especially relapsing staphylococcus affections of the skin, where there is a lack of production of antibodies, due to the patient's capacity for pro-

ducing antibodies being worn out. Many times brilliant results, not infrequently failures, are met with in the treatment by vaccines of relapsing furuncles, sycosis, and pustular dermatitis. His results vary in the treatment of eczema. It is the pustular, weeping or vesicular type that is most favorably affected, but there were many negative results. About 50 cases of rosacea were treated, 25 of whom were private patients, who could be better followed than dispensary patients. In cases where the rosacea is complicated with acne pustules, the albus vaccine not only causes the acne to disappear, but diminishes the rosacea, and there is improvement also in the cases of pure rosacea. He admits, however, that hygienic and constitutional measures are also necessary. With regard to ordinary acne, acne vulgaris, Gilchrist still considers the vaccine treatment of great value. He has found that a stock bacillus acnes vaccine made in the hospital laboratory is as effective as an autogenous one. The following may be cited as a very saving clause in his argument as to vaccines in acne: "Patients with severe acne have still to be treated with a great deal of painstaking care, and one cannot rely on vaccine therapy alone. It is necessary to give careful attention to diet, to the regulation of the normal functions, to fresh air and exercises, to the expression of all comedones, since vaccines have no effect on comedones at all, and in many cases to the application of mild x-rays, and finally to the use of suitable lotions or ointments." He refers to the indiscriminate and unscientific use of acne vaccines by hundreds of physicians throughout the United States with very unfavorable results. He now recommends an initial dose of 10 to 20 millions, then wait for the negative phase that occurs from the third to the eighth day and is shown by the appearance of new lesions or the flaring-up of old ones, and after these have subsided, give another injection, and so on for three or four injections, when a period of rest is to be taken.

Gilchrist notes some beneficial results in blastomycetic dermatitis by treatment with a filtrate from a three months' old culture of the blastomycetes.

It was thought, since tuberculin ointment had been used with some success in treating lupus vulgaris, that ointments made with the staphylococci, streptococci, trichophyton tonsurans, etc., might in the same way be found to be valuable. The organisms were therefore mixed with a cold cream base, in the strength of ten per cent., and this was applied to various cutaneous affections, especially those due to one or the other of these organisms, or where they were secondary invaders. The results were not favorable in papular, pustular and weeping eczemas of the legs, arms and face, but there was great benefit in two cases of eczema and pruritus about the anus. Also benefit was produced in a few cases of sycosis vulgaris. An ointment of the bacillus acnes produced some interesting improvements, but could not be regarded as successful on the whole.

In summing up, Gilchrist points out the necessity of having an intimate knowledge of bacteriology and immunology in attempting to treat skin diseases by means of vaccines, giving the preference to autogenous vaccines, and warning against the use of the commercial mixed vaccines. He admits that this treatment by vaccines has not been so successful as it promised, but yet regards it as a valuable aid, especially in acne and the staphylococcic forms, and perhaps occasionally in eczema. He thinks that the use of ointments made up of organisms cultivated from the skin offers a hopeful chance for investigation.

RESEARCH STUDIES IN PSORIASIS.[2]

Schamberg, with his assistants, Kolmer, Ringer and Raiziss, has conducted an elaborate and important series of investigations on the subject of psoriasis in the dermatological research laboratories of the Philadelphia Polyclinic and College for Graduates in Medicine. In the investigations no attempt has been made to prove any theory of the causation of psoriasis, a subject about which at the present time, as in that of Auspitz, practically nothing is known. The researches were conducted on two lines, one bacteriological and pathological, the other physiological-chemical; and the work was carried out with the intention of recording the findings, whether of a positive or negative character. A summary of their conclusions from their bacteriological and pathological investigations is as follows:

1. Nine of 48 cases of psoriasis, or 18.7%, gave positive Wassermann reactions, using an alcoholic extract of luetin liver as antigen. With antigens of cholesterinized alcoholic extracts of human and beef heart over 28% or 22 cases reacted positively. From a clinical study of the patients whose serums were studied, the positive tests cannot all be attributable to syphilis, although this might be true of a few of them; on the other hand some significance must be attached to them, which future research alone can reveal.

2. Using for antigens aqueous and alcoholic extracts of psoriasis scales and of a larger number of cultures of organisms isolated from lesions, complement fixation was not found to occur with 10 sera from active cases of psoriasis. These results would indicate that either the true antigen was not present in the extracts of scales and culture used, or that the psoriasis antibody, if it exists, was not present in the sera in sufficient amount to inactivate complement with the extracts used in this study.

3. Sixteen different organisms were isolated from 57 cultures from 24 cases of psoriasis. No organism was found that could be regarded as bearing an etiological relationship to the disease.

4. An unidentified diplococcus was found in 5 psoriatic lesions and in 1 blood culture, and is deserving of further study.

5. The use of anaerobic methods and special culture media, composed of the scales and secretions of psoriasis, did not show the presence of any special parasite.

6. Numerous growths of scales in moist chambers showed the presence of diplococci, but no unusual organism or fungus.

7. Investigation with the ultramicroscope discovered the presence of a motile bacillary body in 17 out of 19 cases of psoriasis. In 18 other dermatoses these were found in 3 instances. These bodies are being further studied.

8. Cultures and microscopical examination of fluid secured by blister over psoriasis lesions yielded negative results.

9. Vaccine treatment carried out with vaccines made from a large number of different species of organisms found in psoriasis lesions, yielded indifferent and inconclusive results.

10. Inoculation experiments on monkeys, including the implantation of buttons of psoriasis skin, scales, serum and defibrinated blood, were negative in one to six months after inoculation.

With regard to metabolism in psoriasis, a great many contributions on this subject have appeared during the last twenty years. These observations have been based chiefly on clinical examinations, with sometimes an analysis of the urine. The writers' research on the metabolism of psoriasis was directed primarily to a study of the protein metabolism. In the experiment all of the patients were kept in private rooms at the Polyclinic Hospital, which were on the same floor as the laboratory, so that the excreta could be transferred to the examining room as quickly as possible. The results of a careful study of the protein metabolism of eight psoriasis patients are reported with much detail. The summary and conclusions of their investigations show:

1. That on a given protein diet a psoriatic subject eliminates less nitrogen in the urine than does a normal individual on a corresponding diet. The urinary nitrogen in some of the patients reached a level lower than has even been recorded.

2. Patients suffering from psoriasis exhibit a remarkable retention of nitrogen. This retention appears to be proportional, in a general way, to the extent and severity of the eruption present.

3. The nitrogen is retained to a greater degree than has been observed in connection with any other condition, and is, furthermore, retained with great ease even on a diet low in nitrogen and insufficient in caloric value, and one on which a normal individual would fail to maintain equilibrium.

4. Experiments with urea feeding show conclusively that the nitrogen retention cannot be attributed to any disturbance in the eliminative capacity of the kidneys.

5. Patients with extensive psoriasis may lose very large amounts of nitrogen in the exfoliated scales, which consist of almost pure protein.

6. The retention of nitrogen in most of the cases was greater than could be accounted for by the protein lost in the scales, and it may persist even after scaling has ceased, and the eruption has virtually disappeared.

7. A low nitrogen diet has a most favorable influence upon the eruption of psoriasis, particularly when the latter is extensive. Making all reservation suggested by scientific caution, there can be no doubt that severe cases of psoriasis improve under such a diet, almost to the point of disappearance of the eruption.

8. Conversely, a high nitrogen diet exhibits an unfavorable influence on psoriasis, commonly causing an extension of the eruption.

9. Whether a high nitrogen diet can stimulate an outbreak of psoriasis in a psoriatic subject, who is at the time free of the eruption, has not yet been determined.

10. The great proliferation and exfoliation of cells by the skin in psoriasis demand a large supply of protein, which can only be procured from the lymph and blood streams. This protein supply may be derived from the ingested food, and a possibility exists that the great demand of the diseased skin for protein may also be satisfied by the protein reserve in muscle tisssue, which thus may become depleted and later require restoration.

11. A protracted, low protein diet may diminish the proliferative activity of the skin by diminishing the supply of the principal building material, namely, protein. On the other hand, a high protein diet may stimulate the proliferative activity of the cells by furnishing an abundant supply of the necessary protein.

12. The writers are unwilling, at the present stage of their studies, to venture an hypothesis as to the primary cause of psoriasis.

ARTIFICIAL ERUPTIONS FROM CRUDE COAL TAR.

Brocq,[3] who was one of the first to advocate the use of pure coal tar in the treatment of oozing and highly inflammatory eczemas, calls attention to certain cases of artificial dermatitis produced by this agent. He still maintains the view that of all preparations actually known that are of value in drying up rapidly a vesicular eczema, either of the true or of the seborrhoic type, crude coal tar is the one best tolerated by a large majority of patients. Exceptions, nevertheless, occur, in which it is necessary to suspend the treatment immediately, on the appearance of certain indications that the individual skin is intolerant of this application. Hallopeau and François Dainville have reported a case of acute bullous dermatitis following the frequent applications of methylene blue and coal tar in a patient suffering from persistent urticaria. Brocq agrees with the reporters that this eruption was due to the applications of coal

tar and not to the methylene blue, as his experience with methylene blue since 1897 has been that inflammatory reactions with abundant exudation sometimes occur when it is employed in eczematous subjects, but never a bullous eruption.

With coal tar, on the contrary, he has found that in certain comparatively rare instances, the application of coal tar may provoke the appearance of large bullae, which are more or less characteristic of this procedure. This occurs especially in eczematous subjects, on the upper and lower limbs, and especially on the lower part of the legs. In a case cited, that of a man of 37 who had entered the hospital for a generalized eczema, coal tar applications had been made to the lower part of the legs, the places where there was the most exudation. Soon afterward enormous bullae, filled with yellowish serum, appeared on the regions that had been treated with the coal tar. Later on a modified coal tar paste produced an eruption of small bullae. In other cases, an oxide of zinc paste containing varying proportions of coal tar, produced an intense redness of the skin, after several days of application. But the characteristic sign of this dermatitis is the production of vesicles and bullae. Often the bullae are of very large size like those of pemphigus, with very resistant walls, the raw surfaces left after the breaking of these lesions persisting often for a very long time.

Brocq thought at first that these accidents were due to a bad quality of coal tar, but careful investigation showed that it must be explained by individual intolerance. Consequently Brocq counsels caution in the use of crude coal tar, using it in pure form or incorporated in pastes only on very small surfaces at the beginning, and using it generally only when one is sure that it will not produce any poisonous effect. Also it is important not to repeat the applications very often, and to suspend its use when one sees the skin assuming a certain red tint. He considers it regrettable that these relatively rare occurrences should throw discredit on an application that is most useful in rebellious pruritus and in exudative eczemas.

PEMPHIGUS TREATED BY QUININE INJECTIONS.

Leszczynski[4] in Lukasiewicz's clinic in Lemburg has attempted the treatment of pemphigus with quinine intravenously. Quinine was recommended by Mosler in 1890 in cases of pemphigus, and for ten years quinine has been employed in most cases of pemphigus at the Lemburg clinic, with no doubt as to its favorable action. The good results attained in many cases of skin disease by blood-letting followed by the injection of salt solution and the action of intravenous injections of salvarsan in syphilis, stimulated Leszczynski to try intravenous injections of quinine in pemphigus. Three cases of pemphigus, in all of which the mucous membranes were prominently affected, were treated by this method, beginning with small doses of quinine, and increasing up to a grain, given every other day. All the patients asserted that as early as the day after the injections, they experienced less smarting and pain from the oral lesions. The skin proved more refractory to the injections than the mucous membranes, but began to improve after several injections. The writer declares that there can be no doubt as to the very rapid amelioration of the oral and mucous membranes lesions under this treatment, and a less rapid, although marked, improvement of the skin lesions. With regard to permanent improvement, new lesions appeared during the treatment in all three cases. The first patient, to be sure, showed few and slight recurrences, and was discharged well. No return had yet occurred. The second, a more severe case, continually exhibited new lesions during the treatment, although he was free at the time of writing. In the third case, the mucous membrane of the mouth improved more quickly than in either of the others, and remained good during the whole time of observation. On the mucous membrane of the vulva and on the skin, new efflorescences appeared during the treament, and the patient was not free from the trouble. The writer truly says that it may be a question whether the benefit in these cases comes from the quinine or from the salt solution in which it is given. On the one hand, we know that quinine internally has given good results in pemphigus, and on the other hand Bruck and Simon have shown the good effects of drenching with salt solution. On both grounds, therefore, the use of the quinine injections seems to be justified. It would be of interest to know if other bullous and exfoliative dermatoses may be benefited by quinine injections. In a case of exudative erythema multiforme, with bullae and exfoliative changes of the mucous membrane of the mouth, healing of the mucous membranes was attained after four injections of quinine, and no new appearances were observed during the succeeding two weeks. The writer concludes, on the strength of these three cases, that injections of quinine salt solutions have a favorable influence on the course of pemphigus, and hasten epithelial regeneration. They also alleviate subjective symptoms and improve the general condition.

ALOPECIA ATROPHICANS.

Dreuw[5] of Berlin states that alopecia atrophicans is very little known as compared with alopecia areata. It was first described by Brocq in 1885, and consists of bald patches of varying size, seldom perfectly round, but with three and four angles, partly isolated and partly confluent, with inflammatory appearances or subjective symptoms, which lead in the course of years to an atrophy of epidermis and corium and result in permanent baldness. It has been named by Brocq pseudo-pelade. Inasmuch as

this affection occurs in epidemics, Dreuw considers that it ought to be brought more prominently before the general medical profession than has been the case.

In 1910, 200 cases were observed in Berlin schoolboys. The patches corresponded to the description of Brocq given above. The children affected were from 5-14 years of age, all of them boys. The affection began with a small bald spot of rounded or oval shape, with in some cases a few scales appearing. In no case was there a total alopecia. Remains of hairs were sometimes to be found in the centre of the patches. Microscopically no fungus or parasite could be detected. He names this episode alopecia parvimaculata on account of the arrangement in small spots, and regards it as the beginning stage of alopecia atrophicans, inasmuch as the symptoms of the latter affection have been observed in eight of the school children. The fact that no infectious agent could be discovered is not, the writer asserts, sufficient evidence that the affection is not contagious, in view of the epidemic character. On the ground of an epidemic described in Lüdingshausen he considers that there is a form of alopecia parvimaculata non atrophicans which is related to some forms of alopecia areata.

MEDICAL COSMETICS OF THE SKIN.

Kromayer,[6] inventor of the quartz-lamp, takes up first the anomalies of cornification and warns against the free and long-continued use of ointments, paints and powders for cosmetic purposes, which protect the skin from the irritating effects of air, light, and varying grades of temperature, but cause a thinning and diminished nutrition of the integument and subcutaneous fat, which predispose to early senile changes. Such skins are also more susceptible to diseased conditions, and to hyperkeratoses, which in turn lead to eczematous inflammatory conditions. These rough skins, predisposed to eczemas, are wanting in water and in fat, and it is the object of therapeutics to supply the place of these substances. Fats should be applied immediately after soap washings, and before the skin is thoroughly dry, wiping off the excess with absorbent cotton or a bit of linen. Kromayer considers that the pure fats, as lanolin, vaseline, oils, etc., make the skin unpleasantly greasy, and recommends solution of fats in fluid and gelatinous substances, solutions of glycerine and castor oil in alcohol, glycerine in tragacanth or solution of fats in ether. Fatty emulsions, cold creams, etc., are perhaps most valuable of all, as equal parts of lanolin, vaseline and water, or with the addition of glycerine.

For keratoses, radium and the Roentgen rays are recommended, especially on account of their action on the connective tissue, which the writer asserts is also "hardened" in conjunction with the epidermis. These agents should not be used in too feeble doses; it is desirable to push them to the point of a well-marked erythema.

With regard to vascular anomalies, various pastes of sulphur, salicylic acid and resorcin are commonly used in the treatment of rosacea, when there is present also an affection of the follicles. Lassar's schälpaste, and the quartz-lamp are also recommended. When there is hypertrophy of connective tissue, with enlargement of the nose, the Roentgen rays and the quartz-lamp are of great value. The older methods, of scarification and electrolysis, are much inferior. Touching the vessels with the sharp point of the actual cautery is recommended, however, in rosacea, as well as in the case of punctate vascular naevi and linear telangiectases. In the case of flat naevi, radium is preferred to carbon dioxide snow, by Kromayer, or radium in combination with Roentgen rays.

With regard to acne vulgaris, the writer takes the view that the ordinary form at the time of puberty is due to constipation, which causes the absorption of abnormal poisonous substances from the intestinal tract. For local treatment in acne the Roentgen rays are particularly recommended, especially in rotation with stimulating applications and peeling.

The anomalies of pigment are to be treated in various ways, according to the character of the individual lesion. The interesting assertion is made that an intense application of the rays from the quartz-lamp so that bullae are produced, is followed by a permanent and not temporary removal of pigment. He has also used the lamp to lighten the pigment at the borders of patches of vitiligo.

In the treatment of alopecia areata, he considers that the light as applied by the quartz-lamp is far superior to all other methods. He has not, however, been able to make use of this method with advantage in other forms of alopecia.

With regard to hypertrichosis, he speaks of the Roentgen ray treatment for the removal of this condition as useless and to be abandoned. With regard to electrolysis, he displays an acquaintance with the finer points of this treatment which is much inferior to that possessed by the skilled operators in America, where this procedure was devised and developed. Even with an unprotected needle, there should be no danger of scarring in experienced hands. He reports a far larger percentage of recurrences than is necessary, and his method of technic is surely inferior to that adopted by the best American dermatologists.

Reports of Societies.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, April 8, 1914, at 8.30 P. M.

The President, Dr. William D. Robinson, in the chair.

THE SUBJECTIVE AND OBJECTIVE SYMPTOMS OF FAVORABLE AND UNFAVORABLE REACTIONS TO TUBERCULIN.

Dr. Myer Solis-Cohen: Many of the phenomena produced by tuberculin are often unrecognized because they are slight or have not been recorded in the literature. Valuable information as to suitability or unsuitability of dosage is neglected with the result that the appropriate dose is frequently increased instead of being held and the excessive dose often still further augmented, until the well-known book symptoms of a severe unfavorable reaction have been produced. Unless the physician questions his patient closely without, of course, suggesting the nature of the reply, and unless the patient observes himself carefully and reports his symptoms accurately, many of the less well-known symptoms of a reaction will be missed. If the observant physician will note every symptom occurring on the day of and the day after the administration of tuberculin that was not present before the dose was given, he may discover many symptoms of a reaction of which no mention has as yet been made. In order to direct attention to the disregarded and unfamiliar symptoms I have tabulated all the subjective and objective symptoms that have followed the administration of tuberculin in 56 of my patients of whom I had sufficient notes and on whose records I could lay my hands. To this list I have added 45 symptoms of a reaction that have been described by other writers but not recorded by me. I distinguish between favorable and unfavorable reactions to tuberculin and have grouped the symptoms under these two heads. In 56 patients who reacted to tuberculin I observed a total of 91 distinct symptoms, many of which I have not seen previously recorded. It should be borne in mind that this is an analysis not of patients taking tuberculin but only of those who presented symptoms of a reaction to tuberculin. Symptoms grouped under the head of a favorable reaction are detailed under sub-headings of: (1) general or systemic symptoms; (2) changes in the temperature; (3) lung symptoms; those under the head of unfavorable reaction are detailed under (1) general or systemic symptoms; (2) gastro-intestinal symptoms; (3) alteration in the temperature; (4) lung symptoms; (5) pains; (6) eye symptoms; (7) vasomotor phenomena. Symptoms reported by other observers I have recorded under: (1) General or systemic symptoms; (2) local or organ symptoms; (3) skin reaction at site of injection.

REPORT OF A CASE OF OSTEITIS DEFORMANS.

Dr. Eleanor C. Jones: This rare disease of the bones was first described by Sir James Paget in 1876, and is commonly known by his name. The latest statistics show about 175 cases on record of which only about fifty are American cases.

The case reported follows closely the essential features of the cases reported by Paget. The disease in this woman began at the age of 53 years. She has lost about four inches in height, her height now being 4 ft., 11 ins., because of the bowing of the legs and curvature of the spine. Her head is large and square looking; the thorax small and emaciated; clavicles thickened. The spine has the appearance of sinking into the pelvis. The pelvis is wider than normal, and all the long bones are bowed. The arteries are somewhat atheromatous, and the second aortic sound is accentuated and there is a loud systolic murmur present. The urine showed a cloud of albumen. The examination of her blood for Wassermann reaction was negative. The summary of the bone changes found by radiographical examination were those of new bone formation, porosity, a softening arthritis and bone absorption. No suggestions could be made as to the cause of the disease in this patient.

THE CORRELATION OF APPENDICITIS AND OTHER ABDOMINAL AFFECTIONS.

Dr. Levi J. Hammond: Aided by abundant clinical evidence we must conclude that the frequency of the co-existence of abdominal inflammations with appendicitis is more than a coincidence. A critical analysis of the findings in 920 operations at the Methodist Episcopal Hospital, Philadelphia, would seem to indicate that the existence of the appendix establishes an important anatomic and physiologic relation to the remainder of the digestive system. It must, therefore, be considered as a specialized and functioning organ blending with the remainder of the digestive tract. The principal characteristic of the appendix is lymphoid tissue. One property of lymphoid tissue is to produce leucocytes, and it is only after the sclerosed appendix has impaired or destroyed the function of the lymphoid that acute appendicitis develops. As to the demonstrable anatomic relation of the appendix with other abdominal organs I would especially refer to that of the mesoappendix and the ovary by a peritoneal fold extending directly from the former to the latter. This relationship explains the frequent association of the appendix and adnexal disease. Of all the organs the liver is the one which appendicitis causes to suffer most. Epigastric symptoms must be regarded as reflex phenomena caused in the domain of the vagus nerve by irritation in the nerve terminals of the appendix. Gastric dyspepsia in chronic or recurring appendicitis is thus explained, dependent as it is upon trouble within the secretory, motor or vasomotor function of the viscera. Neuralgic or neuritic pains are in like manner referred to the hip, the thigh, or to the thorax as in pneumonia and acute tuberculosis. Chronic duodenal and gastric ulcers would seem to be dependent upon septic thrombi of appendiceal origin. Biliary lithiasis, chronic cholecystitis and hepatitis furnish forceful evidence in support of their origin in part, at least in primary infection of the appendix. Diagnosis must be based upon existence of a painful zone. This can always be elicited at the point where the appendix is located if palpation combined with rectal and vaginal examination be thorough.

Recurrent attacks of supposed typhoid fever have proved to be chronic appendicitis and prompt cure followed removal of the appendix. When differenti-

ation of the various abdominal affections is doubtful and the morbid symptoms justify operation, this should be done through an incision allowing intervention with the viscera and the appendix, with the ovary and the appendix, or with the kidney and the appendix. Faisans says, appendicitis is so frequent that one must always think of it and seek for it systematically by aid of interrogation and a complementary examination as one seeks for syphilis and alcoholism.

OUR EXPERIENCE WITH CROTALIN AT THE OAKBOURNE EPILEPTIC COLONY.

DR. N. S. YAWGER: For the purpose of this study a fair group of individuals having idiopathic epilepsy were selected for three months treatment. All but one patient were given an intramuscular injection of crotalin once a week for three months. We began with 1/200 of a grain gradually increasing it to the strength mentioned in the details of the cases, 1/25 of a grain being the maximum dosage. Because of the psychic effect the purpose of the injections was kept as much as possible from the knowledge of the patients. Briefly stated, our exerience was that two patients were uninfluenced; two were worse during the treatment; one, early in the course developed such intolerant toxic symptoms that further experimentation was unjustified; and the last patient died two and a half months after treatment. While we did not feel that death resulted from the use of crotalin, the patient's disease certainly was not benefited by the treatment.

Book Reviews.

The Practice of Pediatrics. By CHARLES GILMORE KERLEY, M.D., professor of diseases of children, New York Polyclinic Medical School and Hospital. Octavo, pp. 878, 139 illustrations. Philadelphia and London: W. B. Saunders Company. 1914.

This new book by Dr. Kerley contains an immense amount of valuable material. It is, on the other hand, not very well arranged and shows evidence of having been hastily written. It is written from the standpoint of the practitioner and will, therefore, be of great value to practitioners. The vast clinical experience of its author is manifest on every page. It is especially strong in regard to the treatment of diseases, the part in which most books are woefully deficient. No one can read it without picking up many valuable points in treatment, even if one does not entirely agree with the author in all his recommendations. The book should be very useful to physicians, whether they are in general practice or specialize in the diseases of children. It should have a wide sale.

A Treatise on Diseases of the Skin. For the Use of Advanced Students and Practitioners. By HENRY W. STELWAGON, M.D., Ph.D., professor of dermatology, Jefferson Medical College, Philadelphia. Seventh edition, thoroughly revised. Octavo of 1250 pages with 334 text illustrations and 33 full-page colored and half-tone plates. Philadelphia and London: W. B. Saunders Company. 1913.

The last edition of this work appeared in 1910. The present, the seventh edition, although following closely on its predecessor, shows the advances made by dermatology, in the descriptions of more or less recently acknowledged independent disorders that have been added by the author. Among these may be mentioned prurigo nodularis, granuloma pyogenicum, benign sarcoid, and keratosis blenorrhagica. About forty new illustrations have been added, much old matter has been eliminated, and much new matter and many changes in the text have been inserted. In short, the book has been completely reset, but preserves its place as the best text-book from the point of view of students and practitioners in the English language.

Biology. General and Medical. By JOSEPH MCFARLAND, M.D. Second edition. Thoroughly revised. pp. 457. W. B. Saunders Company. 1913.

The first edition of this book was favorably reviewed in these columns and we see no reason to change the opinion then expressed. The author has modified the text somewhat in response to the friendly criticisms of his readers and again presents a book clearly written and containing a vast number of facts with which persons of ordinary education should be acquainted. The value of such a book to students of medicine is particularly evident.

Modern Anesthetics. By J. FREDERICK W. SILK, M.D. (Lond.). New York: Longmans, Green and Company. 1914.

Dr. Silk is one of the leading London anesthetists. His book on anesthesia adds another to the group of excellent English handbooks on this subject by Gardner, Mortimer and Alderson, all of which have been recently reviewed in the JOURNAL (Vol. clxii, p. 576; Vol. clxvi, p. 258, and 423). Like his colleagues, Silk advocates the habitual use of the corneal reflex, whose employment is discouraged by American anesthetists. The book is well illustrated with 36 figures in the text, and is a valuable addition to the manual literature on anesthesia.

Annual Report of the Surgeon-General of the Public Health Service of the United States. Washington: Government Printing Office. 1914.

This report records the activities of the Service for the fiscal year 1913. It is divided into the usual headings of scientific research, maritime and domestic (interstate), quarantine, and marine hospitals and relief. It records an interesting variety of scientific and administrative data. Among the urgent needs of the service are more officers, an additional building for the hygienic laboratory, funds for printing publications, and an appropriation to defray the expense of collecting morbidity reports.

Surgical Diseases of Children. A Modern Treatise on Pediatric Surgery. By SAMUEL W. KELLY, M.D., LL.D. Illustrated. Second edition; revised and enlarged. New York: E. B. Treat and Company. 1914.

The first edition of this text-book was published in 1909. The appearance of this second edition within five years is evidence that the volume has found a place of value in medical literature. Considerable new matter has been added, notably with regard to arthroplasty, club-foot, scoliosis, tonsillectomy and transfusion, but sufficient condensations have been made so that there is an increase of only 25 pages in the total. A series of 62 notes have been transferred from the text to a convenient appendix. There are 295 illustrations. With the exception of Kirmisson's admirable "Handbook of the Surgery of Children," this seems the most satisfactory and available work on an important and often neglected special field of surgery.

An Introduction to the History of Medicine. With Medical Chronology, Bibliographic Data, and Test Questions. By FIELDING H. GARRISON, A.B., M.D. Illustrated. Philadelphia and London: W. B. Saunders Company. 1913.

The purpose of this volume is partly to present a consecutive story of the development of medical sience, partly to record a large number of discrete biographic and historic data in a form readily available for reference. Both aims are very happily fulfilled, and at the same time, the encyclopaedic character of the book does not detract from its literary excellence. There are successive chapters on primitive, Egyptian, Oriental, Greek, Byzantine, and Mahometan medicine; on medicine in the middle ages and renaissance; and on the medicine of the four great succeeding centuries. The text is well illustrated, chiefly with portraits, and there are complete indices of personal names and subjects. The work is a valuable contribution to the literature of medical history, of which it places a comprehensive and scholarly survey within convenient access both for students and for occasional readers.

Spätpsychosen Katatonic Art. Von DR. MED. MAURYCY URSTEIN. Warsaw, Berlin und Wiener: Urban und Schwarzenburg. 1913.

This monograph on late catatonia, which with the author's previous publications is well worth the consideration of the psychiatrist, shows how insufficient are our present methods of diagnosis and classification. The manic depressive in his cases, may and does become in later years a catatonic, exhibiting signs and symptoms which if present in the patient's early life we should not hesitate to ascribe to dementia precox. The presenium ushers in many psychoses, which no matter how they start, whether by manic depressive symptoms, by paranoid ideas or catatonic manifestations end in a large number of cases with the symptoms of catatonia. Urstein's exceptional opportunities in having access to the fine records of Schweizerhof has made possible this demonstration of the insufficiency of the Kraepelinian scheme, but when Urstein goes further and makes catatonia a disease with an underlying internal splitting of the personality as the cause, he leads us into the same difficulties as Kraepelin has, for an inner splitting must be the basis of all functional psychoses, no matter what their character. There must be a destruction of inhibition here, a stimulation there, a falling part somewhere else, and an internal splitting is no more a characteristic of any single group of diseases than inflammation is peculiar to a skin infection or a meningitis. It is a general process, the recognition of which will not help us in the diagnosis of any one condition. Further, we find that his "catatonia" embraces almost the whole of dementia precox, the largest part of manic depressive insanity, the major portion of the psychoses occurring in the presenium and senium, and, therefore, the concept is not of great advantage to us since it does not enable us more intelligently to offer a prognosis or apply treatment. While his cases also are those in which the psychosis has come on after forty years, probably a more searching history into the antecedents of his patients would have revealed the fact that in many cases there was an initial attack in adolescence or in early life. This attack may have been a slight one and have passed without further notice than to call it "nervous prostration," a term of which psychiatrists ought to be especially suspicious.

Nevertheless Urstein has done psychiatry service in the publication of his cases of Spätkatatonie as well as in that of his two other monographs. The three books are earnestly recommended to every psychiatrist.

THE BOSTON

Medical and Surgical Journal

THURSDAY, JUNE 11, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,

101 TREMONT STREET, BOSTON, MASS.

AUTO-SERUM INJECTIONS IN CHRONIC PSORIASIS AND OTHER OBSTINATE SKIN DISEASES.

THE latest thing in dermatology is the use of auto-serum in the treatment of certain inveterate affections, as practiced during the past year by Linser, Ulmann and other German authorities. In this procedure a suitable quantity of blood is drawn and centrifuged, and the serum thus obtained is injected intravenously. The method appears to be practically harmless, and its technic is simple. It has only very recently been introduced in America, and the credit for its first employment here is due Gottheil of New York, who in the *Medical Record* for April 4 published reports of twelve cases,—six of generalized psoriasis, three of generalized eczema, two of pemphigus, and one of leprosy,—treated in his service at the City Hospital, Blackwell's Island. The psoriasis and eczema cases received autogennous serum; the pemphigus and leprosy ones, that of relatives and that of a case of dermatolysis when it was available. In the first two diseases the injections were given once a week,—three or four in number, of from 20 to 30 c.c. each, making about 100 c.c. in all,—before the local treatment, of very mild character, was begun. In the pemphigus and leprosy cases more injections were employed. In the cases of psoriasis the results were wholly admirable, and in those of eczema less decisive, though marked improvement was observed, while in those of pemphigus, although reports of wonderful success in this affection have been published in Germany, there were practically no results at all. In the case of leprosy the benefit from the treatment was unmistakable and quite rapid, though in this disease there is no reason to hope that it will do more than ameliorate the symptoms and improve the general condition.

A second communication on the subject was presented by Gottheil at the May meeting of the Medical Association of the Greater City of New York. Since the expiration of his term of service at the City Hospital, in January, the cases in which he has employed the treatment have been mostly in private practice, and the exigencies of office work have naturally rendered it impossible to administer it to any very large number of patients. The process is somewhat lengthy; the services of a nurse and an assistant, while not absolutely necessary, are desirable for the instrument sterilization, the centrifuging, etc., and the various factors of personal convenience, expense, and individual possibilities and idiosynerasies have to be taken into consideration. As in the first series, the most noteworthy were the psoriases, of which there were five. One of these patients was a physician with the affection chiefly on the palms of the hands, and complicated by a severe radiodermatitis, the result of x-ray treatment, who withdrew from observation before the course of treatment was concluded. Excluding this case and judging from his experience in the other ten cases of the disease now treated, he expresses the positive conviction that in psoriasis the auto-serum method has a peculiar influence for good, which enables one to clear off the skin in one-tenth the usual time, with very weak and innocuous local medication, and without any internal treatment whatever. All the cases were old, extensive and recurrent instances of the disease. In every case the treatment was well borne and caused no inconvenience, and in all, the following effects were observed: Cessation of the appearance of new lesions and diminution in the elevation, redness and scaling of the old ones; very rapid disappearance of the disease,—in from three to seven days after the course of injections, under the mildest kind of local treatment (usually with 2½% chrysarobin petrolatum); and all this without any of the extremely troublesome general dermatitis ordinarily accompanying the chrysarobin full strength medication. Such a gratifying picture he contrasts with the four to

six weeks' treatment with ointments ranging up to 40% of chrysarobin, the daily arsenical injections, up to the very point of toleration, and the daily scrubbings with detergent soaps, etc., which constituted his former plan of procedure. The evidence therefore seems to him conclusive that in psoriasis the blood withdrawal and subsequent serum injection, one or both, have a very pronounced influence in modifying and ameliorating the disease and rendering the skin less susceptible to the irritating effects of local medication, and at the same time more responsive to its remedial action. Whether the treatment has any influence in preventing or delaying relapses, or on the general course of the disease, must be left to the future to disclose.

A few cases, including a chronic urticaria, a generalized lichen planus, a bad pustular acne with large abscesses, etc., are still under treatment, but Gottheil states that he is not prepared to report upon them as yet, except to say that in them the prospect looks encouraging. These cases are of such long duration, so recalcitrant to ordinary treatment, and so prone to show exacerbations and remissions, that he feels that great caution must be exercised in reporting results. He does, however, cite one remarkable case in this second series which is deserving of special mention. The patient had had prolonged x-ray treatment for some abdominal disorder six years ago, and this had resulted in the formation on the skin of the abdomen of an atrophic area, covered with telangiectases. Last autumn it began to show distinct signs of active inflammation, and at one time there seemed danger of a fatal termination. When Dr. Gottheil first saw him the entire area was necrotic, presenting the complete picture of a chronic gangrenous radiodermatitis. Local treatment was almost impossible on account of the exquisite tenderness, and morphine had to be constantly resorted to on account of the intolerable pain present. As the result of one injection of 70 c.c., at the end of a week there was noted a wonderful improvement in the lesion and in the general condition of the patient, who for the first time had been able to sleep without the aid of narcotics. During the month following he was given four injections of nearly 100 c.c. each, there was a rapid and steady betterment, and he gained fifteen pounds, or more, in weight. The ulceration was now clean,—all necrotic tissue having been removed,—and two-thirds healed; and, as the sensitiveness had disappeared, vigorous stimulant local treatment was instituted. Since the results under the five injections had been so satisfactory, it was purposed giving him three more, by which time it was estimated that the ulceration would be entirely healed. After the sixth, however he had a chill, followed by fever and sweating, and as similar phenomena of even greater severity resulted from a seventh injection, the serum treatment was discontinued. The constitutional reaction produced was thought to be probably of the nature of "serum sickness," due to the sensitizing of the organism by the previous injections. At the present time the ulceration is but one-quarter its original size and is slowly healing under local treatment alone. On the whole, the results observed in this case are certainly noteworthy; though, as therapeutic work of this kind is as yet experimental and without data, it is possible that the injections were too large or too near together.

Among those who have taken up the autoserum treatment are Fordyce, MacKee and Howard Fox. In his experience with it Fox has had eighteen cases: fifteen of psoriasis, two of eczema, and one of herpetiform dermatitis. In the eczema cases the results have been unsatisfactory, but in the herpetiform dermatitis somewhat more encouraging, while in the cases of psoriasis they have proved exceedingly gratifying. He has given rather smaller doses of serum than Gottheil, and finds local treatment after the injections to be essential. In his psoriasis cases he employed chrysarobin, and in some instances also covered the lesions with rubber cloth, but the final results have been such as could by no means have been obtained from local treatment alone.

MacKee has employed the treatment in fourteen cases. Eleven of these were of inveterate psoriasis, and he noted in them the same admirable results observed by Gottheil and Fox. Like the latter, he uses the smaller doses of serum, and he usually gives about six injections, at a week's interval, before resorting to local treatment. His local medication is even milder than that of Gottheil. In two cases of herpetiform dermatitis which had resisted all other treatment for twelve years, the skin entirely cleared up in six or eight weeks. Whether the result will be permanent remains to be seen. He has observed no serum sickness, and speaks very encouragingly of this new treatment, which he has found easy to carry out and apparently free from danger.

ANTI-VACCINATION SENTIMENT IN GERMANY.

IN commenting editorially, in the issue of the JOURNAL for April 23, on the Bagshaw anti-vaccination bill, we referred to the minimum frequency of smallpox in Germany, where compulsory universal vaccination is enforced. It appears, most regrettably, that there is an anti-vaccination faction also in that country, as was evidenced by a discussion in the Reichstag on May 23.

"On a motion to appoint a commission composed equally of friends and opponents of vaccination for the purpose of studying the whole question, party lines were completely obliterated and the motion failed only by a tie vote. It was brought forward in answer to numerous petitions for a change in the present law, which has been in force for 40 years.

"The anti-vaccinationists claimed that hundreds of cases occur where health is injured by the practice, and it was pointed out that the official statistics show that 32 deaths were thus caused in Prussia in 1912. They further asserted that managers of stations for obtaining lymph from calves have themselves admitted the impossibility of getting a pure lymph in all cases. The German law does not provide for compulsory vaccination, but the police authorities have everywhere construed it as giving them the right to require vaccination, and when it becomes necessary they use compulsion. The representative of the imperial health office, however, said that there were only eight or nine cases yearly where compulsion was necessary.

"A Socialist speaker claimed that some parents have been punished five or six times for refusing to have their children vaccinated, and some of them were sent to prison. Hundreds of thousands of people in Germany, he added, have to act contrary to their conscience in having their children vaccinated, and the example of England, where a conscience clause was adopted some years ago, was held up for imitation by Germany. The case of Italy was also pointed out as worthy of study; it was asserted that vaccination is nowhere practiced so extensively as in that country, yet nowhere is smallpox so frequent. Dr. Kirchner of the imperial health office answered all this by displaying a statistical table showing a steady reduction in smallpox cases since the present law was passed."

At the moment of our happy escape in Massachusetts from the threatened evils of an anti-vaccination propagandum, we cannot but lament this evidence of unenlightened prejudice among the people who present the best example of the beneficence of vaccination against smallpox.

TYPHOID DEATH-RATES.

IN the year 1913 Boston had a typhoid death-rate of 8.4 per 100,000 population, standing twelfth among United States cities. Cambridge, Mass., was fourteenth, with a rate of 9.2, and Lowell, Mass., fifteenth with a rate of 10. During the three-year period 1911 to 13, Cambridge stood second in the United States, with a rate of 5.6, and Boston and Lowell stood eighth, with a rate of 8.6 each.

Philadelphia, which for many years has had a rather poor reputation regarding typhoid, had a rate of 15.7 in 1913, almost double the rate in Boston. In Chicago during the fall of 1913 there was an increase in the number of cases, the reason possibly being an impure public water supply. It is interesting that New York, the largest city in the country, should have had the lowest typhoid rate in its history, namely 7 to 100,000 of the population. This rate compares favorably with that in various European capitals.

Although in a general way it is fair to attribute a lowered typhoid incidence to improved general hygiene, it must nevertheless often happen, as in fact the variations in the death-rate of various cities seem to demonstrate, that fortuitous circumstances beyond the control of the health authorities must arise from time to time, leading to the outbreak of considerable epidemics. This has apparently always been the experience in regard to this so-called preventable disease and simply serves to emphasize the fact that unremitting precautions should be taken to avoid all possible sources of infection, and particularly with relation to public water supply. The foregoing statistics, compiled and published by the *Journal of the American Medical Association*, are a valuable index of the relative extent of typhoid fever in our larger cities, and if the facts as published stimulate a healthy rivalry to minimize the disease, a step in progress toward the complete elimination of this unnecessary infection will be made.

CENTENNIAL OF YALE MEDICAL SCHOOL.

AT the coming Commencement of Yale University, June 15 to 17, the Yale Medical School will celebrate the one hundredth anniversary of the first conferring of degrees. The occasion

will be observed by special exercises to be held June 15, at which addresses will be presented by Professor William H. Howell of Johns Hopkins University and Dr. Walter R. Steiner of Hartford. An excellent musical program will be furnished in connection with the addresses. On Commencement Day a number of honorary degrees will be conferred to commemorate the occasion. A Life of Nathan Smith, one of the founders of the School, will be issued from the Yale University Press at about Commencement time, and a memorial volume of medical papers, prepared under the editorship of Dr. Horst Oertel, and containing contributions from Drs. Graham Lusk, E. R. Baldwin, John Hartwell, C. W. Field, W. W. Herrick, Charles F. Craig, Samuel W. Williston, and Horst Oertel, will appear as a special number of the *Archives of Internal Medicine*. It is hoped that the University will be able to announce at this time the consummation of the plan for affiliation with the New Haven Hospital and gifts to the endowment of the School, to which reference is made in a note in this issue of the JOURNAL.

MEDICAL NOTES.

RECAPTURE OF EARLY THE LEPER.—Report from Seattle, Wash., states that on June 2 John R. Early, the leper, whose escape from quarantine we noted in the issue of the JOURNAL for May 28, was captured in a local hotel and returned to custody.

DECREASING NUMBER OF MEDICAL SCHOOLS.—The recently published eighth annual report of the Carnegie Foundation for the Advancement of Teaching notes with approval that the number of medical schools in the United States has decreased from 162 in 1910 to 115 in 1913.

A WELSH SCHOOL OF PREVENTIVE MEDICINE.—It is announced that the South Wales and Monmouthshire University College at Cardiff has received from an anonymous donor funds for the erection of a school of preventive medicine. We have become so sure of the mode of infection that, being compelled by the lack of bedding, we put patients with other trouble in the beds which had been occupied by typhus patients. We made no further change than clean sheets and pillow covers, and though in several cases the limit of incubation has passed twice over there has not been a single infection."

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION.—The annual meeting of the American Medico-Psychological Association was held in Baltimore from May 25 to 28, inclusive. On May 26 there was a symposium on paresis. On May 27 the annual address was delivered by Dr. Lewellys F. Barker on "The Relation of Internal Medicine to Psychiatry." On May 28 there was a symposium on eugenics, following which the Association defeated by a large majority a proposed resolution favoring the enactment of so-called eugenic marriage laws.

Resolutions recommending the segregation of the feeble-minded, imbeciles, or other mental delinquents, and the establishment of separate institutions for their care, were adopted unanimously.

Dr. S. E. Smith, of Richmond, Ind., was elected president of the association for the coming year. Dr. E. Brush of Baltimore was chosen vice-president, and Dr. Charles G. Wagner of Binghampton, N. Y., was re-elected secretary-treasurer. Councillors elected were: Drs. H. R. Stedman of Boston, H. M. Green of Milledgeville, Ga., W. M. English of Hamilton, Ga., and C. F. Applegarth of Mount Pleasant, Ia.

ANOTHER XIPHOPAGUS.—Another case of xiphopagous twins was reported in a recent issue of *American Medicine*.

"The mother is a white woman, aged 44; by a previous husband she has a son, who is now 23 years of age, and quite normal. On Nov. 28, 1913, she gave birth to two girl children, both a good deal below the normal standard of full-term development; it is not stated what period of utero-gestation had been reached. They are united by a piece of tough fibrous tissue, about four inches thick and twelve inches in circumference, below the sternum, and reaching nearly down to the umbilicus. They have entirely separate thoracic and abdominal organs, except that the two peritoneal cavities are in communication through the band of union. Possibly it is due to this fact that a curious phenomenon occurs in respiration, for one twin inhales as the other exhales, and *vice versa*. One child is very slightly larger than the other in most of its measurments and appears stronger; this larger twin has a pulse-rate of 130, whereas the smaller one's rate is but 120. The blood of the two children also exhibits differences. The larger child has 6,960,000 red corpuscles per c.mm. and 7500 leucocytes; the smaller one has 6,280,000 and 6335 respectively. The children are progressing favorably, and a photograph reproduced with the description shows them being fed, one from each breast."

AMERICAN SOCIETY OF TROPICAL MEDICINE.—The eleventh annual meeting of the American Society of Tropical Medicine, held in Boston on May 30, was attended by 25 members.

Dr. S. P. Beebe of Boston read a paper on "The Effect of Ultra-violet Light on Protoplasm," and Dr. Fritz C. Hyde of Boston read a paper on "The Occurrence of Malaria in New England." The third paper of the closing session was on "Malaria," by Dr. C. C. Bass of New Orleans. At the morning session those who presented papers were Dr. Phillip E. Garrison of Boston, Dr. John T. Moore of Houston, Tex., Dr. Andrew W. Sellards of Baltimore, Dr. Aristides Agramonte of Havana, Cuba, Dr. Richard P. Strong of Boston, Dr. Milton J. Rosenau of Boston, and Dr. W. R. Ohler.

Dr. Strong, professor of tropical medicine in the Harvard Medical School, presided, and his address was on "Recent Discoveries in Relation to Infectious Diseases in South America." Dr. Charles F. Craig, U.S.A., was elected president of the society for the ensuing year, and Surgeon-General William C. Gorgas was chosen delegate to the executive committee of the Congress of American Physicians and Surgeons, with Dr. J. F. Siler, of New York City, as alternate.

The other officers elected are: First vice-president, Dr. Milton J. Rosenau of Boston; second vice-president, Dr. Bailey K. Ashford of San Juan, Porto Rico; secretary, Dr. John M. Swan of Rochester, N. Y.; assistant secretary, Dr. Allen J. Smith of Philadelphia; councillors, Dr. D. T. Darling of Ancon, Panama Canal Zone; Dr. Henry J. Nichols of Washington, D. C., and Dr. Victor G. Heiser of Manila, P. I.

The next meeting of the society will be held in San Francisco, Cal., in 1915.

BOSTON AND NEW ENGLAND.

MALDEN HOSPITAL TRAINING SCHOOL.—The annual graduation exercises of the Malden (Mass.) Hospital Training School were held in that city on Thursday evening, May 28. The principal address was made by Dr. Carroll C. Burpee, of Malden, and diplomas were presented to five graduating nurses.

TRADE SCHOOL FOR CARDIAC CONVALESCENTS.—In July, 1913, a Trade School for Cardiac Convalescents was opened as an experiment at Sharon, Conn. The institution, which has now nearly completed its first year, has been exceedingly successful medically and financially, and will be continued on its present basis.

HOSPITAL BEQUEST.—The will of the late Sarah M. Coats, of Melrose, Mass., who died on May 17, was filed on May 28 for probate at East Cambridge, Mass. It contains a residual bequest to the Melrose Hospital Association.

YALE MEDICAL SCHOOL.—It is announced that the Rockefeller General Education Board has offered to the Yale Medical School $500,000, on condition that it procure complete teaching and medical control of the New Haven Hospital, that the teachers in the main clinical branches be placed on the full-time basis, and that by July 1 the university acquire or set apart the further sum of not less than $600,000.

MASSACHUSETTS COMMISSION FOR THE BLIND.—The recently published seventh annual report of the Massachusetts Commission for the Blind records the work of that body for the year ended Nov. 30, 1913. During this period 415 new cases of blindness have been reported, and 600 blind persons have been helped to get training or employment. Legislation for the prophylaxis of blindness is suggested, and a number of special reports are appended.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending June 2, 1914. Diphtheria, 58, of which 2 were non-residents; scarlatina, 71, of which 10 were non-residents; typhoid fever, 9; measles, 123, of which 3 were non-residents; tuberculosis, 82, of which 6 were non-residents.

The death-rate of the reported deaths for the week was 17.64.

NEW YORK.

A NEW CHARITY.—In a lecture on "Food from the Standpoint of Energy" at the New York Academy of Medicine, on March 19, Dr. Graham Lusk, professor of physiology at Cornell University Medical College, remarked that it would be a matter of great interest if some benevolent person would establish a restaurant which prepared pork and beans on a large scale and served it hot, with bread and with half a large cup of coffee made half with milk. Possibly in this way, he said, 1000 calories in a well-balanced ration, furnishing the requisite energy for an average adult engaged in light

work, could be sold for about ten cents. It is now announced that Mr. George Bancher will establish in the Bowery such a restaurant, where one may purchase for ten cents a meal of this composition, which will furnish exactly 1000 calories; and Prof. Lusk has written him, "I do not know of a better charity than to give an indigent person a meal ticket for such a place. You may have the opportunity of doing a great piece of educational work."

Scarlet Fever at Auburn Prison.—An outbreak of scarlet fever has occurred in the State Prison at Auburn, involving both the men's and women's departments, and more than a thousand inmates have been attacked. The disease is said, however, to be of mild character.

Columbia University.—At Columbia University Dr. Warfield T. Longcope, associate professor of the practice of medicine, has been appointed to the Bard professorship of medicine, made vacant by the resignation of Dr. Theodore C. Janeway. He also succeeds Dr. Janeway as director of the medical department of the Presbyterian Hospital. Among the honorary degrees conferred at the 160th annual commencement of the university, on June 3, was that of Doctor of Science upon Dr. Aristides Agramonte, professor of bacteriology and experimental pathology in the University of Havana, especially distinguished for work on yellow fever.

Mikveh Pools.—A conference, called by Health Commissioner Goldwater, was recently held to consider the subject of "Mikvehs," the cleansing pool baths, whose regular use is required by the Jewish faith. These pools have been made the subject of a bacteriological investigation by Dr. Manheimer of Columbia University, and independently by the Health Department. They showed that the Mikveh pools, as at present conducted, are a serious menace to the health of the people using them, and indicated the need of steps to render them sanitary. While no definite measures have as yet been formulated, the department believes that the enforcement of regulations similar to those recently adopted for floating baths would prove feasible. These provide for a preliminary cleansing shower bath, and include regulations regarding the cleanliness of the water in the pools.

Tuberculosis.—The Weekly Bulletin of the City Health Department has published a table giving figures relating to the occurrence of tuberculosis during the first quarter of 1914, and comparison with previous figures shows that the number of voluntary renovations in premises infected with tuberculosis has been steadily increasing. This is regarded as a very encouraging sign, indicating a better conception, by owners and agents of property, of the necessity for preventive measures, and of a greater readiness to comply with the requests of the department to do such work.

Mortality for Week Ending May 30, 1914.—There were 1547 deaths and a death-rate of 14.46 per 1000 of the population reported during the past week, as against 1323 deaths and a rate of 12.85 for the corresponding week of 1913, an absolute increase of 224 deaths, and an increase of 1.61 points in the weekly rate, which increase is equivalent to a relative increase of 168 deaths.

The following causes showed an increased mortality: scarlet fever, diphtheria and croup, typhoid fever, cerebrospinal meningitis, diarrheal diseases, acute respiratory diseases, pulmonary tuberculosis, nervous diseases and violence. There were ten deaths from sunstroke reported during the past week. Those causes showing a decreased mortality were measles and whooping cough. The mortality from digestive diseases, heart diseases, Bright's disease and nephritis was about the same.

Viewed from the point of age grouping there was an increase of 54 deaths of children under one year of age; between one and five years the mortality was approximately the same, between five and sixty-five years of age there was an increase of 122 deaths; and at sixty-five years and over there was an increase of 40 deaths, that is, all groups showed a considerably increased mortality except for the period of one to five years of age.

The death-rate for the first twenty-two weeks of 1914 was 15.29 per 1000 of the population, as against 15.43 for the corresponding period of 1913, a decrease of .14 of a point.

Appointments in State Department of Health.—The following appointments in the State Department of Health are announced: Member of the Public Health Council, Dr. T. Mitchell Prudden, emeritus professor of pathol-

ogy, Columbia University; consulting pediatrician, Dr. L. Emmett Holt, professor of diseases of children, Columbia University; director of the Division of Vital Statistics, Dr. Cressy L. Wilbur, chief statistician, United States Bureau of the Census. The latest issue of the *Health News*, which is the new title of the monthly bulletin of the department, is a "school principals' number, and opens with addresses to the school principals of the state by John H. Finley, LL.D., president of the University of the State of New York and commissioner of education, and Dr. Biggs, head of the Health Department. The latter states that he will in the future endeavor to make the monthly bulletin of special service to the school principals, and through them to the teachers and children, as well as to local health officers and other health workers. It will be the aim of the editor to include in each issue timely and important material under the heading "School Health Lesson."

HOSPITAL SOCIETIES FOR CLINICAL STUDY.—The organization of a society for clinical study has been ordered in each of the hospitals of the City Health Department. Each member of the staff will hereafter be expected to devote himself, during his spare hours, to the pursuit of some special topic or branch of medicine, and will be granted leave of absence from the hospital during stated hours each week for the practical study of the special subject assigned him.

HOSPITAL BEQUESTS.—Among the charitable bequests in the will of Mrs. Lina V. Happel of Brooklyn, N. Y., are $15,000 to the German Hospital of Brooklyn and $5000 to the Hospital for Ruptured and Crippled, Manhattan.

7. *KIEFER, G. I., AND FERRY, N. S. *Some Experiences with Bacterial Vaccines in Scarlatina.*
8. SEFF, I. *Retroperitoneal Hernia of the Appendix into the Ileoappendicular Fossa.*

3. Lankford discusses the determination of pulse-pressure in general practice and in life insurance work, and cites several cases which demonstrate its value. He finds the auscultation method more satisfactory than palpation. One of the cases cited is particularly interesting. A farmer, aged 27, was examined for insurance and recommended as a first-class risk by the examiner. The blood-pressure was reported as systolic 120 mm., diastolic 55 m.m. Suspicions of the low diastolic reading, the Company requested a re-examination after vigorous exercise. This showed rapid pulse, marked arrhythmia and an aortic murmur. The applicant would have been accepted but for his abnormal pulse-pressure.

7. Kiefer and Ferry report encouraging results from the vaccine treatment of scarlet-fever. Their vaccine is made from two organisms obtained from the posterior naso-pharynx of scarlatinal patients—a streptococcus and the micrococcus "S," described by Schultze. [L. D. C.]

11. FISHER, H. M. *Autoserotherapy in Fibrinoserous Pleurisy.*
12. BLOCK, S. *A New Psychosis.*

5. Brodhead reports a case of vagitus uterinus, the authenticity of which he expects will be questioned as usual. He did not hear the uterine cry himself, but he has absolutely no doubt of the correctness of the report of the two internes who did hear it. The patient was on the service of the Post-Graduate Hospital, New York. The second stage was prolonged and the interne had introduced his right hand into the vagina, preparatory to applying the left blade of the forceps when he heard a loud cry. The crying continued at intervals from that time until the head was extracted, thirteen minutes later. The child had a good color and was in good condition when born and was normal in every way during the puerperium. [L. D. C.]

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

MAY 23, 1914.

6. *Percy, J. F. *Best Methods of Discouraging the Activity of Inoperable Cancer. A Study of Heat in Cancer.*
7. Gunn, F. H., and Fairbrother, H. C. *Deep Wound of Brain.*

1. Lovett's article, though not suited to abstracting, is of very practical value and well analyzed.

4. Griffith's article contains a large mass of statistics boiled down and covers the symptomatology well.

5. Neuhof describes the technic of this method, its advantages which are distinct in certain cases, and also a case of collapse apparently due to the drug used and not to the method employed. He is in favor of this method of anesthesia in many shoulder and arm operations.

6. The author quotes Nidal, who states that the benefit derived in carcinoma treated by vaccines, etc., is solely from the heat generated by the reaction. The various reports of malignant growths diminishing in size after erysipelas assume a new significance with this theory in mind. The author believes that we can hope for the eradication of cancerous growths by attacking them through their vulnerability to heat. He then details his own experiments and technic. He believes the successful treatment of cancer depends more on the question of heat than on the actual cauterization. [E. H. R.]

15. *Hill, R. *Congenital Pyloric Stenosis.*
16. *Kerr, J. M. M. *Operative Treatment for Malformations of Uterus and Vagina.*
17. Birnie, J. M. *A Method of Exposing the Pelvic Portion of the Ureter.*
18. Stark, S. *Technic Employed in Excision of a Carcinomatous Urethra.*
19. Bartlett, W. *A Simple Meat Method of Sterilizing Catgut; aften Ten Years' Use of It.*

1. The author devotes most of his paper to the technic of scopolamine-morphine anesthesia to produce painless labor. He considers x-ray and radium in treating malignancy valuable, but they may be very dangerous.

3. Horsley's article is beautifully illustrated with cuts showing his technic. He believes that blood-vessel suture is valuable in certain transplantations of organs, in repair of injuries to vessels, in replacing segments of vessels necessarily removed at operation, and in transfusion, which he preferably performs by suture of artery to vein.

6. Beckmann's analysis of the complications following surgical operations in 6825 cases in the Mayo Clinic in 1913 is very interesting. There was a percentage of .017 of infections, or 117 cases; 87 cases had pulmonary complications, none of which were fatal,—.012 per cent. These are divided as follows: Acute congestion, 21 cases; pleurisy, 18 cases; bronchitis, 21 cases; broncho-pneumonia, 12 cases; lobar pneumonia, 15 cases; thrombophlebitis, 14 cases. Figures seem to show that patients with infections are not more prone to have thrombophlebitis than the so-called clean cases. Acute dilatation of the stomach, 3 cases. There was one case of empyema of the chest following transplantation of right ureter for extrophy of the bladder. Three cases of bowel obstruction, 4 cases of cystitis, 1 post-operative miscarriage following appendectomy, 2 cases of neuritis, 2 of arthritis, 6 of tonsillitis, 3 of acute dilatation of the heart (all in thyroid cases), 3 cases of bleeding from wounds following severe jaundice, 3 cases of parotitis. None of these cases were fatal.

8. Dickinson's article on technic is beautifully illustrated by drawings and cuts. It is of practical value.

9. Lewis finds experimentally that cortical bone, free of its periosteum, endosteum, and marrow, will retain its vitality and proliferative powers when subdivided into small fragments and replaced in the tissues. Contact with living bone is unnecessary for the growth of these transplants. Transplanted fascia may take up the nutritional and limiting functions of periosteum.

13. Sampson, in an exhaustive article, shows that under the influence of an ectopic pregnancy there is an increase in the size of the uterus, which is due to two factors,—hyperemia and thickening of the endometrium.

15. Hill believes that all cases of pyloric stenosis in infancy submitted to operation should be fed on mother's milk. He believes operation is indicated when a tumor is present. Surgical treatment has a lower mortality than medical and the relief is immediate.

16. Kerr's article is well illustrated and of practical value. [E. H. R.]

2. Recent studies have shown that tuberculosis in guinea-pigs, after ten days from infection, can be diagnosed by tuberculin tests. Each has made comparative experiments with the cutaneous and intracutaneous injections of tuberculin for the purpose of determining which of these methods is of greater merit. According to his results, the intracutaneous reaction occurs more characteristically and earlier than the cutaneous reaction, and therefore this test is the more satisfactory for obtaining an early positive reaction in the first stages of the experimental disease.

11. Schlesinger states that tuberculosis of the stomach is not an extremely rare disease, but is difficult to recognize. Four types of lesion have been reported: 1. Tubercular ulcer at the pylorus. 2. Hypertrophic changes at the pylorus without ulceration. 3. Sclerotic and chronic inflammatory processes at the pylorus due to tubercle bacilli. 4. Tubercular adenitis around the pylorus with perigastric adhesions.

Clinical symptoms in any of these types of the disease are not characteristic; gastric lavage does not show constant findings; the x-ray picture is not typical; and a local tuberculin reaction is dangerous to attempt on account of the possibility of a resultant perforation. Hence the diagnosis, clinically, is usually overlooked.

Schlesinger reports a case which came to autopsy and which showed a localized tubercular abscess starting in the submucosa of the pylorus, and draining by perforation into the stomach and duodenum. Tubercles were found in the muscularis and serosa around the cavity.

A somewhat similar case has been reported by Mathieu-Rémond. Hence Schlesinger believes in pathological classification of tuberculosis of the stomach, a fifth type must be recognized, consisting of a circular tubercular abscess in the submucosa of the pylorus wall. [R. F.]

5. During the past year, Breuning has collected eleven cases of paratyphoid infection out of 326 babies suffering from various types of gastro-enteric disease. The diagnosis was made by blood or stool culture or by agglutination tests.

Breuning recognizes clinically two types of paratyphoid fever. The first and less severe type resembles typhoid. The second type has symptoms of hemorrhagic enteritis. It is characterized by a weak, rapid pulse, and by profuse diarrhea with mucous stools of foul odor. Its etiology is not explained, though Breuning believes that infected milk may play a part.

These observations are reported for the practical purpose of emphasizing the importance of bacteriological studies in the feverish diarrheas of infants. By such studies Breuning considers that important factors may be discovered in the production of intestinal diseases.

11. Scheidemandel has devised a portable thermostat for the incubation of blood cultures and other bacteriological investigations made in private practice. The instrument consists essentially of a wide-necked thermos cylinder containing a rack for test tubes and agar plates. It is simple and affords a means for making blood cultures at the bedside, and for avoiding the customary exposure of the infected media to heat or cold or sunlight which is usually obtained between the time that the culture is taken and incubated in the laboratory. [R. F.]

5. *STANGE, W. *On Prognosis after a General Anesthetic.*
6. JULINSBURGER, O. *Dial-Ciba, a New Sedative and Hypnotic.*

4. d'Agata, having in mind the frequency and danger of inhalation pneumonia after operations of this sort, has carried out metabolism experiments on two patients who were fed by rectum for ten to twelve days after operation. These investigations, which were exhaustive, prove that a patient can perfectly well subsist for this length of time after operation on nothing but nutrient enemata. He advises this measure, and in addition mentions favorably their technic following operations, which is to have the patient sitting up for twenty-four hours after operation, and then to allow him to get up, out of bed.

5. Stange suggests, as a test of the cardiac muscle before operation, investigation of the length of time a patient can hold his breath without discomfort. He has the patient, sitting up in a chair, take one deep breath and hold it as long as he can. In a series of

cases he finds that a normal person can easily do so for 30 seconds, that those with lung conditions and moderate mitral disease vary between 20 and 30 seconds, and those with severe heart lesions are under 20 seconds. As definite examples of the last group he gives,—

Insufficiency of aortic valve .....15 seconds
Chronic myocarditis .....17 seconds
Large aneurysm of aortic arch .....10 seconds

In view of the above he considers that a general anesthetic is contraindicated if a patient cannot hold his breath 20 seconds, and that if it is absolutely necessary to use one, ether is infinitely safer than chloroform. [R. H. M.]

21. Hausmann describes again his method of mapping out tumors, abnormalities and exudates within the peritoneal cavity by means of his "Gliding and Deep Palpation." He illustrates the article by diagrams showing his findings, and the case histories, operative results or autopsy findings for comparison. He believes that this method will give more reliable information than will radiography, in cases where the two methods disagree, and that the surgeon will be aided very greatly by his ability to use it. "The method," Hausmann says, "is to former methods of palpation as a modern chronometer is to an old sun dial."

22. Heimann and Fritsch applied Abderhalden's carcinoma test in 34 cases. In the great majority of cases the test proved its reliability, the reaction being especially strong when carcinomatous tissue from the same organ as the one suspected of malignancy was used. In two cases the test differed radically from the clinical diagnosis, and in both its correctness was proved later. In every case giving a positive test, cancer was found. [G. G. S.]

8. With the Bang method for studying the sugar content in the blood these authors, working at Copenhagen, have studied a series of normal individuals and some pathological conditions, such as nephritis, diabetes mellitus and a few other cases. They conclude that the normal sugar content of the blood is 0.1 when determined by this method. Their variations ranged from 0.06 to 0.12. Usually in healthy people after a test meal containing 100 grams of sugar there is a variable increase in the sugar content of the blood in different people. The same also occurs after ordinary meals. In nephritis there is usually hyperglycemia, which is not dependent upon increase of blood-pressure, but upon other complications. In cases of gastric diseases, hyperthyroidism and neurasthenia no hyperglycemia was found. In pancreatic disease a hyperglycemia existed. In hyperglobulae there was an increase of blood sugar, due to the increased amount of reducing substance in the blood corpuscles. In diabetes the blood sugar was increased in fasting conditions as well as after mealtimes. Glycosuria may occur, however, without increased sugar in the blood, due to renal factors. The estimation of blood sugar is of good diagnostic and prognostic value. [C. F., JR.]

2. MOLLARD, J., AND DUMAS, A. *"Gallop Rhythm" in the Course of and During Convalescence from Typhoid Fever.*

1. Marañon shows a striking relationship between hypersecretion of the stomach and hyperthyroidism. This relationship does not seem to hold in the advanced cases of Basedow's diseases. In the latter, because of prostration and asthenia, a decrease or absence of acidity is the rule. When hypersecretion is associated with the signs of increased thyroid activity it yields not to direct gastric treatment, but to that which brings relief to the over-excited thyroid gland. This is accomplished spontaneously, by the use of organic anti-thyroid substances or by extirpation of the gland. This as a matter of proof is considerable. In addition one must add the frequent association of these two conditions. Finally, hyperchlorhydria, like hyperthyroidism, may be provoked by artificial intoxication with organic extracts. [L. H. S.]

As a result of his experiments, Pignatti believes he has demonstrated that it is possible to restore the continuity of the interrupted vas with vasal segments, whether arterial or venous, also with segments of vas from the same animal, or of tube from the same species. Invagination of the vas into the transplant assures the best result, though there may be some stenosis of the lumen. [R. M. G.]

Miscellany.

REORGANIZATION OF THE STATE BOARD OF HEALTH.

IN last week's issue of the JOURNAL we published a communication from Dr. A. K. Stone relative to the proposed reorganization of the Massachusetts State Board of Health. The following letter to the daily press by Dr. George W. Gay on the same subject seems to deserve republication as a valuable contribution to the discussion of this important question:—

"If the State Board of Health is ever to be reorganized, the present conditions offer a peculiarly favorable opportunity for carrying out the necessary plans.

"1. After thirty-three years of exceptionally efficient and valuable service, Dr. Walcott retires. He has achieved an international reputation as a wise and practical sanitarian.

"2. We have an executive who is thoroughly in sympathy with the best ideals pertaining to public health. Instead of rushing blindly forward in his efforts at reform, he calls to his aid experts who have the confidence of the scientific world and defers to their judgment in all pertinent matters. This is the true spirit. It merits the support of the public.

"3. Public health occupies a position of importance today never before attained in this country. Only men of the highest qualifications, similar to those of the retiring chairman, are capable of directing them successfully. While the board has done excellent work in the past,

considering the limitations imposed by the state, in the opinion of many reliable authorities the time has come by reason of the growth of the work and the demands of the public for a change in the organization of the board.

"4. As this is an age of individual responsibility, a board with one head and a cabinet or council would seem to be the best plan. The health commissioner should give his entire time to the work. The salary should be sufficient to command first-class talent. There should be no politics in the appointments.

"5. Dr. Walcott should have received a salary for his services. The physicians in this state do too much work for nothing. Why should they be required to serve the state for nothing, in positions as important as the chairmanship of the Board of Health? The citizens of Massachusetts are not mendicants. Hence a paid Board of Health is a step in the right direction.

"It by no means follows that all of the unpaid boards of our charitable institutions should be replaced by paid supervision. Many of the present boards are doing satisfactory work at a reasonable expense to the state. There would seem to be no good reason for a change under those circumstances.

"The two principal essentials of efficient and satisfactory management of the charitable institutions of this state are, first, a harmonious board of trustees, and, second, the right sort of a superintendent. Without the latter, the best results are impossible. With the right kind of a superintendent fairly good work may be accomplished even under a wrangling board of trustees. The trustees are responsible for the efficiency of the superintendent, the governor and council for the trustees.

"Political appointments, here as elsewhere, are liable to result unsatisfactorily. Paid trustees will do no better work than the unpaid. This is largely a personal equation. No one should be required to give all, or even a large proportion of his time to the state for nothing.

"With the right kind of a superintendent many of our unpaid boards do not need to give an unreasonable amount of time to their duties. Plenty of public-spirited, broad-gauged persons with no axes to grind are available for service on the unpaid boards. In the opinion of most of the disinterested authorities the character of their service leaves little to be desired either in efficiency or in expense. For these reasons it would seem wise to leave most of the unpaid boards alone. The State Board of Health is an exception to the rule."

AMERICAN DOCTOR STUDIES TYPHUS.

An American doctor, Clarence D. Ussher, has received hearty and public thanks from the vali of the Turkish vilayet of Van for his "humane zeal and care for the sick" in the recent epidemic of typhus among the Turkish soldiers quartered in the city of Van.

Van, the city, is the center of the Turkish provinces of the same name, in the northeastern corner of Asiatic Turkey. On its eastern border the vilayet joins Persia, while on the north it is very near the Russian Caucasus. The city is on the shore of Lake Van, a large sheet of water whose surface is 5500 feet above tide level. The city is said to have been built by Semiramis, and strange and interesting inscriptions and carvings are found in and about it.

Since the American Board of Foreign Missions began work there the mission has been through war, famine, pestilence and massacre, and the epidemic of last winter will take its place in the history of calamities which Americans have helped the people to fight.

The Turkish military authorities were not insistent on cleanliness and sanitation, and after the epidemic started it made rapid headway so that over 2500 soldiers are known to have died of the disease. Dr. Ussher was active wherever he was permitted to serve, but had not access to the barracks or to the military hospital. In the Board's hospital, however, and in going about among the sick in the camp and in the city he made careful study of the disease, and says:—

"We have proved very conclusively in our hospital that the only means of infection is vermin. Our nurses have been thoroughly exposed to every form of contagion from the breath, desquamation, discharges, constant association day and night, and all this in an over-tired condition, and not one of them contracted the disease. The typhus patients have been put in the same ward with surgical, pneumonia, dysentery, and even confinement cases, and not a single patient has become infected in the hospital.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FROM MAY 4 TO MAY 23, 1914.

May 2, Asst. Surgeon N. R. Sullivan, detached, Canacao Hospital to *Villalobos*.

May 4, Medical Inspector N. J. Blackwood, Commissioned from September 29, 1913.

Asst. Surgeon M. H. Stenhouse, M.R.C., Commissioned April 4, 1914.

Asst. Surgeon W. A. Stoop, M.R.C., Commissioned April 4, 1914.

May 6, Medical Director T. A. Berryhill, detached, Navy Yard, New York, to Naval Hospital, Great Lakes, Ill.

Surgeon C. M. DeValin, to Navy Yard Station, Portsmouth, Va.

P. A. Surgeon R. E. Stoops, detached, Marine detachment, Pensacola, Fla., to *New Jersey*.

Asst. Surgeon J. W. Boyce, M.R.C., resignation accepted May 14, 1914.

May 7, P. A. Surgeon L. M. Schmidt, detached, *New Jersey* to *Louisiana*.

May 8, P. A. Surgeon W. H. Halsey, detached, Naval Medical School, Washington, D. C., to *Montana*.

May 8, Surgeon C. St. J. Butler, detached Medical Supply Depot, to home and wait orders.

P. A. Surgeon A. E. Lee, detached, Marine Detachment, Peking, China, to *Galveston*.

P. A. Surgeon M. A. Stuart, detached, *Galveston* to Marine Detachment, Peking, China.

Asst. Surgeon W. E. Bradbury, M.R.C., Naval Hospital, Philadelphia, Pa.

May 11, Asst. Surgeon L. L. Pratt, to Philadelphia, Hosp tal.

Asst. Surgeon J. G. Omelvena, to Newport Hospital.

Asst. Surgeon J. V. Howard, to Mare Island Hospital.

Asst. Surgeon H. M. Stenhouse, M.R.C., to Las Animas Hospital.

May 14, Surgeon J. S. Taylor, detached, Naval Training Station, Great Lakes, Ill., to *Illinois*.

May 15, P. A. Surgeon R. W. DeDowell, to *Ozark*.

P. A. Surgeon J. B. Kaufman, from *Ozark* to Great Lakes Training Station.

May 16, Surgeon Lewis Morris, detached, Fleet Surgeon, Asiatic Fleet, to treatment civil hospital, Shanghia, China.

Asst. Surgeon N. R. Sullivan, detached, *Villalobos* to treatment Civil Hospital, Honkow, China.

May 19, P. A. Surgeon W. B. Owens, detached, Marine Detachment, Managua, Nicaragua, to *Talahassee*.

May 22, Act. Asst. Surgeon C. K. Miller, revocation of appointment as Act. Asst. Surgeon to take effect May 22, 1914.

May 23, Surgeon F. L. Benton, detached Receiving Ship, Navy Yard, Norfolk, Va., to Marine detachment, Pensacola, Fla.

P. A. Surgeon W. H. Connor, detached Naval Hospital, Boston, Mass., to *Isle De Luzon*.

P. A. Surgeon J. B. Mears, to Naval Training Station, St. Helena, Va.

Asst. Surgeon F. H. Bowman, M.R.C., to Naval Hospital, Boston, Mass.

SOCIETY NOTICES.

THE AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. —The seventeenth annual meeting of the American Gastro-Enterological Association will be held at Hotel Chalfonte, Atlantic City, N. J., on Monday and Tuesday, June 22 and 23.

FRANKLIN W. WHITE, M.D., *Secretary*.

THE PSYCHOPATHIC HOSPITAL.

74 Fenwood Road, Boston.

THE SECOND ANNUAL CONFERENCE on the Medical and Social Work of the Psychopathic Department of the Boston State Hospital will be held in the Assembly Room, four to six p.m., Friday, June 26, 1914, under the auspices of the Trustees of the Boston State Hospital. (Brookline or South Huntington Avenue cars; allght at Fenwood Road.)

PROGRAM.

I. Introductory Remarks. Dr. Walter Channing, Chairman Board of Trustees, Boston State Hospital.

II. The Prophylactic Functions of the Psychopathic Hospital, with Special Reference to Admissions of the "Not-Insane." E. E. Southard, Director.

III. The After-Care Program and Results of the Psychopathic Hospital, Boston. A. Warren Stearns, First Assistant Physician, in charge of out-patients.

IV. Further Notes on the Economic Side of Psychopathic Social Service. Mary C. Jarrett, Director Social Service.

V. High-grade Mental Defectives in a Group of Adolescents Studied at the Psychopathic Hospital. Thomas H. Haines, First Assistant Physician.

VI. Genetic Factors in One Hundred Cases of Psychoneurosis (Out-Patient Department). Donald Gregg, Assistant Physician, Out-Patient Department.

VII. A New Point Scale for Measuring Mental Capacities. Robert M. Yerkes, Psychologist.

VIII. Experience with the Martin Electric Threshold Test in Psychopathic Cases. G. P. Grabfield, Interne.

IX. Experience with the Lange Colloidal Gold Test in Various Cerebrospinal Fluids. H. C. Solomon, Interne.

X. Cases to Illustrate Symptomatic Psychoses of Cardiorenal Type. Frankwood E. Williams, Assistant Physician.

XI. On the Margin of Error in Psychopathic Hospital Diagnoses. A. Warren Stearns and E. E. Southard.

XII. Points Concerning Salvarsan Therapy. H. M. Adler, Chief-of-Staff.

(For convenience of social workers and physicians, the more social papers have been placed early and the more medical papers late on the program.)

RECENT DEATHS.

DR. L. M. BAKER, who died of cardio-renal disease on May 27 at Lynn, Mass., was born in 1869. He received the degree of M.D. from Boston University in 1894, and since that time had practised his profession in Lynn. He is survived by his widow and by one son.

DR. EMIL GRUENING, of New York, died from cerebral endarteritis on May 30. Dr. Gruening was born in Hohelsalza, Prussia, in 1843, and came to this country in 1862. He was in active service with the Seventh Regiment, New Jersey Volunteers, during a considerable portion of the Civil War, and in 1867 was graduated from the College of Physicians and Surgeons, New York. He practised in New York, and became distinguished as an eye and ear specialist. Among the positions which he held were, surgeon to the New York Eye and Ear Infirmary, consulting ophthalmic surgeon to the German Hospital and Dispensary, and consulting ophthalmic and aural surgeon to Mount Sinai Hospital and the New York Infirmary for Women and Children. Dr. Gruening had the high honor of being elected president of both the American Ophthalmological Society and the American Otological Society.

DR. ARTHUR W. SWANN, who died in New York recently, was born at Chattanooga, Tenn., in 1880. He graduated from Harvard in 1903 and from the New York College of Physicians and Surgeons in 1907. Since 1909 he had been an instructor at the latter college and assistant physician at the Presbyterian Hospital. He is survived by his widow and by two children.

AMOS LAURENCE MASON, M.D., a Fellow of the Massachusetts Medical Society, died at Albany, N.Y., June 5, 1914, aged 72 years. He was a graduate of Harvard College in the Class of 1863, was in the Harvard Law School 1863-1864, and graduated from the Medical School in 1872. He was house physician to the Massachusetts General Hospital from 1871-1872; Boston Dispensary and Carney Hospital, 1874-1878; visiting physician Boston City Hospital, 1878-1903.

A POSSIBLE FACTOR IN THE PRODUCTION AND DISTRIBUTION OF EDEMA.*

By Frederick C. Shattuck, M.D., Boston.

Is there one among us who has not been struck, if not puzzled, by the curious distribution of edema, especially in cases obviously of mechanical obstruction to the circulation? We see, for instance, two cases of mitral disease with failure of the myocardial compensation. The physical signs and symptoms taken altogether indicate lesions similar in kind, as well as degree, and also an approximately equal myocardial weakness. The parallelism between the two cases may be accentuated by an equal rapidity and degree of improvement under, for all practical purposes, identical treatment. The sequence of events is mechanically impeded circulation, dilatation of the right heart annulling compensatory hypertrophy, over-plus of blood in the venous system, stasis, dropsy. A difference in the degree of the dropsy in the two cases may be readily accounted for by differences in the lesion, valvular, myocardial, or both, which elude any means now in our powers to estimate. But it would seem that the distribution of the edema should be essentially the same. It is, however, notoriously not so. In one case we see dropsy chiefly or only in dependent parts, especially the legs; in another the great serous sacs are markedly involved with a varying degree of stasis in the lungs, liver and kidneys and little or no anasarca; in still another stasis shows itself mainly in an enlarged liver; in short, seemingly similar mechanical conditions show results which vary far more widely than one would, off-hand, expect.

Long ago a possible, at least partial, explanation occurred to me. I have not seen it in print or heard it suggested, and venture to lay it before you, keenly realizing its hypothetical nature, and how far removed it seems, at present, from direct evidence. The Bertillon system shows that by a sufficient number of accurate measurements any person can be distinguished from every other person. Even more remarkable proof of the individuality of the individual is afforded by the fact that no two persons have the same finger prints. Is it not at least possible that analogous variations may exist in the texture of the tissues, of the organs, in the blood, or one or another of its constituents, which may be a factor in the distribution of edema?

In the urticarias, perhaps especially the giant form, and in angio-neurotic edemas, a nervous element must play an important part; but it would seem possible that individual peculiarity of tissue may play a part in the localization of the striking superficial changes.

* Read before the Association of American Physicians, Atlantic City, May 12, 1914.

ON THE SIMULTANEOUS OCCURRENCE AND INTERRELATION OF BASEDOW'S DISEASE AND TABES.

By Hans Barkan, M.D., San Francisco, Cal.,

Formerly Instructor in Pathology, Harvard Medical School; Assistant in Ophthalmology, Stanford University Medical School.

[From the II Eye Clinic, Prof. Fuchs, Vienna.]

Pierre Marie in 1892 was the first to call attention to the simultaneous appearance and possible interdependence of the symptoms of Basedow's disease with those of incipient or already well developed tabes. In a clinical lecture on the vascular apparatus, as affected by tabes, he says, "les lésions et ces troubles sont multiples et peuvent frapper de façons diverses le coeur et les vaisseaux. En connextion avec ces troubles vasculaires j'aurai l'occasion de vous parler d'une complication signalée tout récemment: le goître exophthalmique." Since Marie's remark on the subject very little has been written about it. Sattler in "Die Basedow'sche Krankheit" issued as a part of Graefe-Sämisch's "Handbuch der Augenheilkunde" mentions and gives a short abstract of the cases reported: by Joffray, 3; Barie, 1; Sechchieri, 3; P. Marie and Marinesco, 1; Ingelhans, 1; Moebius, 1; Lewinek, 1; Timotheef and Mannheim, 2; Kollait, 1; Hudovering, 1; Charcot, 1; Delearde, 1; Wiener, 1; Cohen, 3; Bernhardt, 1. Oppenheim, Eppinger, Strümpell and von Mehring refer to the condition in a few words. In view of the small number of reported cases and the scarcity of literature on the subject, I shall review the salient points as found in a study of the reported cases and literature. Oppenheim in his "Lehrbuch der Nervenheilkunde" raises several interesting points as regards tabes, from the standpoint of the observer also interested in Basedow,—that in tabes epiphora, without local disease of the tear-conducting passages, or tic-like winking of the upper lid, or hyper-esthesia in the neighborhood of the eye, may be found as part of a fifth nerve lesion. These conditions are also not infrequent ones in Basedow's disease. Interesting for the same reasons are the following remarks: "To be especially regarded in early tabes are a number of symptoms displayed as the effect of lesions in the territory of the vago-accessorius. Chief of these is the habitual frequency of pulse, which in not an inconsiderable number of cases may be found early in the disease." In tabes also there may exist, as Oppenheim points out, signs and symptoms directly referable to diabetes mellitus, so that one may be led to the diagnosis of tabes with diabetes, of diabetes with tabes, or finally admit the two to be coexistent, if not dependent

upon each other in these cases. Westphal's sign, paresthesias, lancinating pains, paralysis of ocular muscles, loosening and shedding of teeth, impotence, may be found in diabetes. Williams and Marinesco have in a few rare cases of clinically well marked diabetes even found typical atrophy of the posterior columns. Addison's disease may also show a few symptoms usually associated with tabes, such as Westphal's sign; in one case Bernardi showed a degeneration of the posterior columns. Of tabetic symptoms, which are often among those of the sufferer from Basedow's disease, Oppenheim mentions psychic anomalies, disturbances of general nutrition, motor-weakness, tremor, discoloration of the skin, and diarrhea. The occurrence of Basedow's disease at the same time and as a possible result of other diseases, has been noted a number of times. Walzberg reported a sarcoma of the cranial floor with optic neuritis and Basedow, Oppenheim a hemorrhagic destruction of the posterior inner capsule, with hemi-anesthesia and hemi-ataxia in a woman of 42, who had had Basedow's disease for half a year; the same author also a case of hemi-anesthesia and hemi-ataxia caused by hemorrhagic destruction of the posterior inner capsule, showing shortly after this symptom of Basedow's disease; Joffray and Ashard a combination of Basedow's disease and syringomyelia, as also did Spillman; Moebius and Gordon cases of Basedow's disease with paralysis agitans; Savage, one combined with progressive paralysis; Reynolds a case of disseminated sclerosis and Basedow; Ziegel, Graves' disease combined with scleroderma and a positive Wasser mann reaction.

The symptoms of Basedow's disease followed in the train of the symptoms of the others mentioned in all but one of these cases, and in such fashion that the authors suggest the other disease to have acted in some way as the "Auslösendes Moment." Its occurrence immediately after or during the course of hysteria and various psychoses, of which are to be especially mentioned the melancho-manic type, dementia precox, and hallucinatory paranoia, is a not uncommon occurrence.

Finally a direct if short statement is made as regards its occurrence coincident with tabes: "Most frequently we find tabes combined with hysteria, occasionally with epilepsy, seldom with myasthenic paralysis and diabetes; very seldom indeed with Basedow's disease." Sattler expresses himself as follows regarding the combined picture of tabes and Basedow's disease: "The coexistence of Basedow's disease and tabes appears on the whole to be very infrequent. There exist, however, a number of cases where the coincidence of these diseases has been surely established. If the characteristic symptoms of both are well developed the diagnosis offers no difficulty. On the other hand, if only a few signs of the one or of both exist, it is questionable as to how far one may go in assuming the combination of Basedow's disease and tabes to be present; for we know that in exceptional instances a transient absence of the patellar reflex may occur in Basedow's disease as well as parapareses almost simulating ataxie, with paresthesias of various kinds, and that on the other hand, as Charcot has pointed out, tabetics not infrequently show habitual tachycardia, and that often in the early stages of their disease, as also states of anxiety with tachycardia and arrhythmia of almost the character of an angina pectoris. Again quoting P. Marie in his original lecture on the subject, "Donc fréquence dans le tabes d'un des symptomes cardinaux du goitre exophthalmique, la tachicardie."

Bernhard Sachs in Osler's System, volume on "Disease of the Central Nervous System," does not mention the disease picture, nor does the picture as such receive recognition or even mention in other text-books except those of Oppenheim, von Mehring, Lewandovsky and Sattler, already quoted. Yet, as P. Marie says at the close of this lecture, illustrated by clinical cases: "Cette coincidence de la maladie de Basedow et du tabes est-elle donc un fait extrement rare? Eh bien non, Messieurs!"

Judged by the history and physical findings of the following cases, I believe P. Marie's opinion to have been correct, and that the coincidence of these diseases and a possible relationship when they are so coincident, has been somewhat neglected in our literature and teaching.

CASE 1. The patient sent by Professor M. in Krakau, who in 1911 had found a visual acuity of 6/9 with +3 sp. both eyes. Color perception somewhat diminished. The patient admitted having contracted lues 24 years ago, and had been treated thoroughly with mercurial injections. In 1902 he had been given a glass to read with because of an internal ophthalmoplegia. Both papilla had begun to show slight discoloration since 1896. In 1912 bilateral exophthalmus had been noted. His wife had borne one healthy child; had had two abortions.

Physical Examination. Male, 66 years old, presents an unusually emaciated appearance; the thyroid is slightly and uniformly enlarged, soft, no pulsation. Pulse varies between 102-110 a minute. The protruded tongue and extended hands tremble slightly. Marked bilateral exophthalmus. Hertel, 27. Lid margins widely separated, movements of eye in all directions normal, the right eye, however, often turns outward (Moebius). Graefe's sign absent, Stellwag's present. Both pupils enlarged, left more so than right; pupillary reaction to light and convergence completely absent. The right papilla chalky white, the temporal half showing a shallow excavation; this is also the condition of the left papilla. Margins of the disc sharply outlined; vessels unchanged. The right patellar and tendo Achilles reflex present but weak, the left ones absent. Romberg indicated. In the territory of the right ulnar nerve a subjective feeling of "going to sleep"; an area of anesthesia, band-shaped, over the right mammary region. No lancinating pains, no headaches. Wassermann reaction positive. The patient has taken iodides for many years.

Case 2. Marie M., 42 years. The patient complains of an unsteady gait during the last five years, and that this is increasing. She has noticed a diminution in vision since several months; during this time she has also lost a great deal of weight, perspired freely and felt extremely nervous and "jumpy"; she has noticed her exophthalmus since one month. She also complains of sharp, "tearing pains" in her leg. Of tabetic signs shows unequal and dilated pupils R-L. No reaction to light, convergence reaction unimpaired. Both optic discs are quite gray, temporally, of a slightly yellow gray color in their nasal halves. Disc margins clear cut, retinal vessels normal. Both patellar and tendo Achilles reflexes absent. Romberg marked. The walk is of a markedly ataxic character. No paresthesias. Wassermann positive; marked bilateral exophthalmus. Hertel, 28. Von Graefe's and Dalrymple's sign present. Pulse varies between 115-120; marked tremor of extended hands and tongue; thyroid gland easily palpable, no pulsation. Vision both eyes, 6/24. The visual fields show marked concentric narrowing, especially for red.

Case 3. Alfred M., 52 years. The patient admits lues 15 years ago, states that he was treated at that time with repeated mercurial inunctions. He presents a mixed picture of tabes and Basedow, the signs and symptoms of the latter causing him to consult the clinic; tall, thin, extremely nervous, quick and abrupt in movement, with a roving, unsteady glance. Marked exophthalmus. Hertel, 28. Moebius, Graefe, Dalrymple evident; marked fine tremor of extended hands and tongue. Pulse 120. He perspires very easily and has lost a good deal of weight recently. The thyroid is barely palpable, no thrill, no bruit. Both pupils considerably wider than normal, equally so, reacting neither to light nor accommodation. Both patellar and tendo Achilles reflexes absent. Romberg barely indicated. An area of hypalgesia from the 4th to the 13th rib, right side. Belly reflexes somewhat tardy and barely perceptible. Fundus normal. Vision, B. E. 6/6. Wassermann positive.

Case 4. Isidor W., 58 years. Typhoid fever when 15; gonorrhea at 20; luetic infection denied; married, first 2 children still born, then 4 healthy children. For 5-6 years, loss of sensation in ulnar nerve territory of right arm. Later atrophy of thenar eminence, right hand. Exophthalmus for last 10 years. Had lost a good deal of weight up to 1½ years ago, but since then has gained 10 lbs. Perspires easily and freely, is nervous and excitable. Has had urinary retention relieved by catheterization for two years. Sexual ability not impaired. In the last two years he has stumbled and fallen frequently. Has undergone several inunction treatments, about the time and extent of which he is uncertain. Examination shows exophthalmus of marked degree. Hertel, Moebius, Graefe, Stellwag absent. Very marked intention tremor of the hands, tremor of extended tongue. Pulse, 120. No enlargement of thyroid gland. The dorsal surface of both hands show a diminution of sensibility and unequal perception of painful stimuli. Marked atrophy of thenar and antithenar eminences as well as interossei. Both patellar and tendo Achilles reflexes absent. Romberg well marked. Fundus normal. Vision, B. E. 6/6. Pupils contracted, no reaction to light, reaction to convergence present. Wassermann negative.

Case 5. Eduard R., 43 years. The patient presents himself because of failing vision. He shows a right sided ophthalmoplegia externa of marked degree, which had appeared first six years ago, had changed for the better occasionally, but has become markedly worse during the last year. Slight paresis of the facial of the same side. Deep and superficial reflexes normal. No Romberg. Pupillary reaction normal. Vision, B. E. 6/18, not improved by glasses. Fundus, papillae uniformly light gray in color, sharply outlined, retinal vessels unchanged. The field of vision shows a uniformly concentric contraction for white of moderate degree, but of marked degree for all colors. In addition to the above tabetic signs he presents a moderate degree of exophthalmus. Hertel, 24. Dalrymple present. Graefe and Moebius absent; thyroid easily palpable, no pulsation; the extended hands and tongue show a slight tremor. Pulse, 120 to 130 a minute. States that he has felt restless and nervous during the last weeks, has perspired markedly and had constant diarrhea; loss of weight said to have been considerable. He admits having acquired lues 25 years ago. No treatment. Wassermann positive.

Case 6. Albertine Sch., 31 years. The patient presents herself complaining of diplopia. States that she also "saw double" the previous year, lasting 6 weeks. She is found to have a paresis of both superior oblique muscles. The right pupil is constantly somewhat larger than its fellow, and reacts less promptly to light; reaction for convergence normal. The right Achilles reflex cannot be elicited even with Jandrassek's manoeuvre. Patellar reflexes normal. No areas of anesthesia. Romberg absent. The fundus normal; both discs show well marked physiological excavations. In addition to the above signs of a tabes incipiens there are present an enlarged thyroid, a fine tremor of extended hands and tongue, pale moist skin, a pulse of 110 and a moderate degree of exophthalmus. Hertel, 23. Has lost 25 lbs. in the last 4 months, during which period she has also become very irritable and unstable in her emotions, easily excited and worried. During this time she has been treated at a medical clinic in Vienna, taking the following prescription every week: Kalil jodati 5,0, aquae fontanae 200/0. She admits having contracted lues 10 years ago. Wassermann positive.

Case 7. Adele B., 42 years. The patient presents herself because of the exophthalmus. This she has had to a slight degree for two years, accompanied by a decided feeling of general weakness, marked perspiration and tachycardia, these all having increased markedly in the last six months. Of the signs of Basedow's disease, she shows enlargement of the thyroid, without pulsation or bruit, tremor of extended hands and tongue, tachycardia, a pulse of 120 and exophthalmus. Hertel, 27. Von Graefe's and Dalrymple's signs present. Moebius absent. There has been a decided loss in weight; both pupils wider than normal, slight anisokorie, reaction to light absent. Patellar and tendo Achilles reflexes absent. Slight Romberg. No ataxia. Fundus in all details normal. Wassermann positive.

Case 8. Therese M., 46 years. The patient presents herself because of failing sight. Vision found to be B. E. 6/18, not improved by glasses. Examination of her visual field by Bjerrun's method shows

a concentric contraction of the field for red with temporally a U-shaped indentation corresponding to a similar but slighter one for the white field, which was also concentrically narrowed. The fundus showed a well marked primary atrophy of both optic discs. She states that she noticed diplopia lasting a month, six years ago. In the last three to four years she has often vomited green matter, suffering at the time with severe pain in the epigastric region. At present she complains beside the failing sight, of great nervousness, of "feelings of anxiety" accompanied often by profuse perspiration, especially at night. She feels weak and is short of breath; in the last three months has lost 15 lbs. in weight. Examination shows an easily palpable thyroid, no pulsation, a slight degree of exophthalmus. Hertel, 22. The right eye stands in a convergence of 10°, possibly due to the former abducens paralysis, with consequent contracture of the antagonist,—diplopia cannot be elicited now. Graefe, Dalrymple, Moebius, absent. Pulse, 125. Fine tremor of extended hands and tongue. Patellar and tendo Achilles reflexes absent. Pupils normal. Wassermann positive.

Eight cases of this character in the space of three months among the ambulatory of the clinic lead Fuchs to the not unnatural supposition that this condition is more frequent than has been up to now supposed; and as many come to an eye clinic first, partly because of the exophthalmus, partly because of their failing sight, due to tabetic nerve atrophy, partly because of the motor instability which is often felt as a dizziness and referred to the eyes, a good number have no doubt been overlooked.

Careful survey of these histories and physical findings can leave no doubt that all were afflicted at one and the same time with Basedow's disease and tabes. A survey of the literature, scanty as it is, the finding of 8 of these cases within the last three months in one clinic, and granting the very probable supposition that many of these cases exist but are overlooked, neither ophthalmologist nor internist examining Basedow patients with reference to tabes, which, as we have seen, is in nearly all these cases incipient, its symptomatology often masked by the more striking picture of the Basedow component, surely dispels the assumption that when found together, we are facing two absolutely separate and independent affections happening to coincide in time.

In the further discussion of the possible relationship of the symptoms in these cases, I believe it will become clear that we are not dealing with coincidences. Summing up the cases it can be said: All but 1 show a positive Wassermann reaction; all show the cardinal symptoms of tabes; Argyll-Robertson, absence of patellar or tendo Achilles reflex; all but 2 Romberg's sign; 3 cases in addition to the cardinal symptoms primary optic atrophy; 1 case marked ataxia, 2 cases distinct areas of paresthesia, 1 lancinating pains. Six of the 8 admit having had lues. There can be no doubt that we are dealing with 8 tabetics. As a group they present just as typical a picture of Basedow's disease. All show exophthalmus, a pulse varying from 95-120, and fine tremor of extended hands and tongue; a palpable and enlarged thyroid, though to slight degree in all but one; all complain of perspiration, of restlessness and nervousness. All show marked loss of weight. The summing up of these signs and symptoms meets the very justified warning of Von Mehring: "One must beware of the diagnosis of 'secondary Basedow' or 'forme fruste,' if a few of the great number of symptoms of hyperthyroidism are found in connection with paralysis agitans, tabes, certain psychoses, in the course of chronic iodide intoxication, with chlorosis, or during excessive thyroidin treatment." Two of my cases had been taking iodides and it is a question as to whether they belong in the type picture. They are instructive in another regard, however, to be referred to later. There is no case in which any one of the signs here ascribed to Basedow, or the combination of them in any case, could be counted as belonging to the tabes, with the exception of the rapid pulse. This, however, in view of all the other signs and symptoms of Basedow's disease, can be safely reckoned as belonging to this latter.

The "time occurrence" of the two diseases is an aspect of the combination on which Sattler has collected some interesting data. In the cases of Joffray, Barie, Sechchieri, P. Marie, and Marinesco, the two were found coexistent at the first examination of the patient, who could not tell which group of symptoms had commenced first. In a second case of Joffray and in one of Moebius', the symptoms of both appeared at the same time; in Moebius' case lightning pains, diplopia, tremor and tachycardia were all equally marked and had appeared at the same time; Argyll-Robertson, optic atrophy, absence of patellar reflex, Romberg, exophthalmus and struma were found combined at the first examination. In the cases of Lewinek, Timotheef and Mannheim, and in one further case of Joffray the cardinal symptoms of tabes had existed for five years, to be followed by typical Basedow; in one case only was exophthalmus missing. In the further cases of Charcot, Moebius, Deliarde, Wiener, Cohen and Mannheim, Timotheef and Bernhardt, the Basedow antedated the tabes, but it is to be remembered in this connection that the Basedow symptoms are usually first noticed by the patient, incipient tabes being then found on examination.

It is to be noted that in all these cases the specific infection occurred years ago, with the Basedow in all cases years after the infection, appearing in practically all cases shortly before, at the same time with, or shortly after, the symptoms of tabes.

There is not a single case reported, in fact, where the Basedow antedated the specific infection and where in that case tabes-Basedow were found coexistent later, although in several cases struma had existed for years. In my own

cases, Case 1 presented tabetic symptoms antedating the appearance of exophthalmus by 18 years, Case 2 tabetic symptoms antedating those of Basedow by 5 years, Case 3 had suffered from Basedow for 2-3 months previous to examination and at that time presented marked tabetic signs. Without question these have existed for a longer period. Case 4 states having noticed loss of feeling in the distribution of the ulnar nerve 12-15 years ago, exophthalmus since 8 years. Case 5 had had paralysis of the third nerve 6 years ago and had noted symptoms of Basedow in the last few months only. Case 6 had had diplopia a year ago and had noticed exophthalmus with loss of weight since 4 months. Case 7 had noticed the exophthalmus 2 years ago and was found to have objective marks of tabes, whose beginning must certainly be traced as far back as that. Case 8 had well marked optic atrophy, had had diplopia 6 years ago, had had gastric crises 3 years ago; her Basedow symptoms are of only a few months' duration.

These cases form almost a "type picture" and lead to a consideration of the possible relationship existing when the diseases are found in the above manner. Do they exist simply and solely as a chance happening? I think this may be dismissed in view of facts already stated, as extremely improbable. Has one led to the appearance of the other, directly or by an intermediate process? If so, which has favored the development of the other? Have we finally a type of luetic manifestation sui generis?

As to the second question: Curshman has recently reported in two tabetics intermitting symptomatic Basedow occurring with other paroxysmal appearances on the part of the vegetative nervous system, in conjunction with gastric crises and hypertension of blood pressure, the appearance of all the cardinal symptoms of Basedow's disease. V. Malaise has also reported two cases from Marie's clinic. In the opinion of these authors we are dealing with an affection of the sympathetic and have a condition analogous to disturbances of other organs, such as the stomach, depending on disturbed equlibrium of the vegetative nervous system. Curshman believes that we are dealing with a primary tabetic lesion of the cervical sympathetic, which, when it oversteps certain bounds, leads to a swelling and hyper-secretion of the thyroid (in the sense of Abadie, Jannescu and others), which again leads to the thyreotoxic symptom complex of Basedow's disease. Bauer, in a discussion of Curshman's cases speaks of them directly as "thyroid gland crises" appearing as the result of intermittent disturbance of the gland enervation. That the Basedow in these cases in any way favored the appearance of the tabes can be ruled out. None of the cases reported had Basedow extending over many years or appearing occasionally, nor has it ever been proven that any intercurrent disease, acute or chronic, favors the appearance of tabes in a syphilitic, though chronic poisoning, such as with alcohol and nicotine, does seem to act as a factor. While the incident of tuberculous lesions of the lung or lymph-glands is a very high one in the autopsy records on cases of tabes or paralysis (Klippel, Anglade, Calmeil, Seglas, Regis, Goldstein, Marmieres, v. Lucas, Tatusesco and Heilbronner) it seems to me, in consideration of the fact that both tuberculosis and syphilis are so ubiquitous, and that autopsies are more general on tabetics and paralytics as a class, than on any other, most of them dying in state asylums or hospitals, etc., that the coincidence cannot be used in the sense in which Stern attempts to, namely, that there exists a certain bodily habitus peculiar to the majority of tubercular and tabetic patients, and that a coincidence of bodily disposition a priori exists, which renders individuals of this habitus more likely to become tabetics if lues be acquired.

To be considered more seriously in the sense of Stern as expressed by him in "Über körperliche Kennzeichen der Disposition zur Tabes" are his observations on the coincidence of tabes and Basedow's disease.

For the appearance of tabes or general paralysis Stern declares the following triad of factors to be necessary: The "dispositio paralyticans," the luetic infection, and the patho-function of certain glandular organs of internal secretion. He has divided metaluetics into two main groups: that of a tall, rather asthenic type, of weak musculature and sparse hair growth, and into that of a broad-shouldered, muscular, rather hairy individuals. These groups merge into each other in subdivisions: that of the asthenic akromegaloid, the asthenic hairy, the asthenic rhachitic medium height, the muscular broad type, the adipose and muscular adipose type, etc. In these groups he believes to have found certain signs which show that in one group one internal secretory process has suffered derangement of function, or has always over- or underfunctionated, in another group another. For us his remarks anent the disposition to overactivity of the thyroid in one class are of interest. This is the asthenic type; longlegged and of sparely developed secondary sexual characteristics, according to the views of Tandler, Holmgreen and Stern, the result of an overactivity of hypophysis and thyroid gland. Stern believes that this group of tabetics has been subject to a relative hyperthyroidism during years of involution, and as just this group is the one representing the greatest number of tabetics, and as just in this group are mainly found, according to Stern, the combination of tabetic symptoms with those of Basedow, comes to the conclusion that in the development of tabes, as regards this group at least, hyperthyroidism plays a leading rôle.

As opposed to this class, in this regard, stands that of the group of short, muscular, hairy individuals. Here Stern finds no sign or few of hyperthyroidism. In this group fall most of the cases of optic atrophy, cases which in them-

selves are to be differentiated from the asthenic group, in that their tabes is of a relatively mild sort, both as regards subjective symptoms and ataxia. This has also been the course of the cases showing akromegaloid type and tabes, and of this whole class of short, sturdy, hairy individuals, Stern rather believes in a hypophyseal disturbance of function as a leading factor in the development of tabes.

My cases would, according to the hypotheses of Stern then, be explained as tabes developing after a primary luetic infection in individuals suffering from hyperthyroidism. This may not have evidenced itself actively, except in so far as its influence in forming the asthenic group was concerned, until the time of the appearance of tabetic symptoms. In the two of my cases taking iodides, the appearance of hyperthyroidism might then be conceived of as a formerly latent process being activated. Goldflams, Roux, Clark, Pineles, Krehl, have all seen Basedow appear with iodides in tabes incipiens.

In an effort to group my cases according to the formula of Stern, I find that they fall naturally into two divisions; four of them to be classed among the asthenic, four among the broad-shouldered, muscular group. All, however, showed equally the symptoms of hyperthyroidism. It is also true that the three cases of optic atrophy were in the second group. It may not be out of place here to mention that tabetic optic atrophy is found more especially among well developed robust, rather stocky individuals. Four of my cases are women, four men. In the cases collected by Sattler the ratio of women to men stands at about six to one. About 15 women acquire Basedow to one man. This relationship holds in about inverse order as regards tabes. The preponderance of women in the combination of Basedow and tabes might be explained by their greater susceptibility to thyreo-toxic influences, predisposing to development of tabes in a luetic. The total number of cases, however, is too small to permit of any definite conclusions. This can also be said as regards the conclusions drawn by Stern. While his views are interesting, it will need the observation of many more cases before a definite conclusion as regards the importance of his grouping of tabetics can be made, especially as regards the value of them in reference to prognosis and therapeutics.

Two of my cases had been using iodides. Goldflams and others have reported cases of tabes in which Basedow appeared during a course of intensive iodide administration.

One point of clinical importance, therefore, I believe is worth considering in regard to these cases as a group. In tabetic individuals of an asthenic type,—long-legged, tall, meagre, nervous—especially, if they show any mark of hyperthyroidism,—tachycardia, hyperidrosis, glycosuria, dermographism, increased salivary or lachrymal gland secretion, I believe iodides, because of the possibility of Basedow developing in just this class, to be contraindicated.

A definite conclusion as to the course and factors predisposing to the development of the type-picture, cannot, I believe, be made at present. We know that only about 3½% of all syphilitics develop the so-called "meta-luetic" lesions. Explanations of this fact differ and none of them and no combination of them entirely cover the ground. Erb's school maintains that spirochetes are of various sorts, one kind producing a relatively mild lues often followed by "meta-luetic" developments, while infection by another variety may not cause late syphilitic effects. This view is supported by the experiments of Spielmeyer, who succeeded in growing trypanosomes, killing dogs in from six to eight weeks. In cultures from these animals there was obtained a variety which inoculated into dogs produced typical tabetic symptoms; the cultures obtained from these animals produced in the next series of dogs, the effects of the first inoculation, death in from six to eight weeks. It has hence been experimentally shown that trypanosomes can be so influenced as to alternately produce different types of disease.

The other widely held view is that of the importance of the special bodily constitution of the individual, "meta-lues" being the result of a syphilitic affection in a person so constituted. Chvostek especially has pointed out that an individual's constitution is the product of the relationship of his internal secretory activities. It is very possible that through certain changes in increase or decrease of internal secretion a specific reaction to the virus of a certain disease may be called forth; in this manner the varying reactions as regards the luetic virus could be explained, and the occurrence of Basedow's disease concomitant with tabes in certain cases, becomes more intelligible.

The factor of the primary toxicity of the spirochete,—of its tabes developing potential in the sense of Erb,—may play a part. Stern's constitutional moments certainly do, and the possibility of direct tabetic lesions of the cervical sympathetic in certain cases (though this would not account for the entire picture of Basedow's disease) cannot be denied. That the two diseases do interact and in doing so bear a causal relation to each other as also that the combination is not as infrequent and of much greater importance than has been supposed, are facts which may, I believe, be accepted as established.

It is a pleasant duty to thank Hofrat Fuchs for his permission to report these cases as also to acknowledge my thanks to Hofrat Fuchs and to Professor Marburg for advice and criticism.

OBSERVATIONS ON STERILITY IN THE MALE.*

BY J. DELLINGER BARNEY, M.D., BOSTON,

Genito-Urinary Surgeon to Out-Patients, Massachusetts General Hospital; Assistant in Genito-Urinary Surgery, Harvard Medical School.

THE object of this communication is twofold. First, I wish to point out that in the event of a childless marriage the finger of suspicion points at the woman with shocking frequency. It is almost a reflex act on the part of the physician, to say nothing of the husband. The fault is hers, and even in the absence of some definite abnormality of her genitalia, she falls a ready prey to curette, dilator, or glass plug. Second, I wish to consider, in a general way, the sterile man, and to discuss some of the causes of his sterility.

There seem to be no very accurate figures as to the frequency of childless marriages. According to Huhner (Sterility in the Male and Female, Rebman, New York, 1913), 10% of all unions are sterile. In France the number is put at 20%. But in a general and impersonal investigation of statistics on this point one must not forget that the clandestine, but admittedly widespread use of the many methods for the prevention of conception is a factor of unknown, but immense importance.

Therefore all the material upon which we must base our figures consists only of those comparatively few couples who, anxious to have children, come to the hospital or to the physician's office. Even in such cases there is no general agreement as to the number of times in which the husband is at fault. Hunter (*American Journal of Surgery*, April, 1912) quotes numerous writers whose percentages vary from 1 to 80. Lier and Ascher (cited by Scholtz, *Arch. f. Dermatologie u. Syphilis*, 1910, 101) found the fault to lie with the husband in 71% of the sterile marriages which they investigated. Huhner, in 129 couples, found this figure to be 59%. Kehrer's 40 cases (Huhner, *loc. cit.*) indicted the husband in 35%. S. W. Gross (Huhner, *loc. cit.*) in 192 cases from various authors, found the husband responsible in 17%. Vedder (Huhner, *loc. cit.*), examining 50 husbands, found them sterile in 70%.

In view of these facts it might be supposed that a community such as ours, would proceed with caution under such circumstances. As Belfield (*Journal American Medical Association*, 1912, lix, 1419) aptly says:

"The investigation of childlessness should begin, not with the curettage of the wife, but with the microscopic examination of the husband's semen."

But the facts show the contrary to be true. From one of our largest public hospitals I have collected data of 108 women, in whom a diagnosis of sterility is recorded. Some of these women had been married many years. Three had been married more than once. In justice to the male sex, and to the particular individuals here involved, these patients are not to be included in our statistics.

In 31 cases the records do not contain any statement as to advice or treatment either of the wife or of the husband. Of the remaining 74, 37 were advised to undergo operative treatment, while the remaining 37 actually went through this ordeal. In many this advice was given or an operation performed in the presence of a negative pelvic examination. In only 5 of these 105 women (4.76%) was the husband first examined!

If these operative procedures had led to the much desired pregnancy we might feel somewhat justified. But failure is written in large type over the results. Twenty-five of the women operated upon were followed for a year or more. Only 2, or 6%, had become pregnant or borne children. An attempt to examine the husbands of the remaining 23 cases met with poor success. He rarely can be approached, and

* Read at a meeting of the Obstetrical Society of Boston, December 23, 1913.

even when found to be sterile, usually as a result of his own indiscretions, he shrinks from the comparatively simple procedures which might result happily. However, 4 such husbands were examined. Two were evidently normal in every respect. In the other 2 the semen contained no spermatozoa, and an examination of their genitalia showed evidence of an old gonorrheal infection. One of these men had been married twice, neither wife had ever become pregnant, the present incumbent had gone through two fairly serious operations, yet the husband's powers of procreation had clearly become obsolete years before.

Bearing in mind the figures already given as to the frequency of the sterile husband, it is fair to assume a similar percentage in the cases here presented.

One might suppose that in hospital practice the pressure of work furnished an excuse for an inexcusable blunder; one might further suppose that this does not apply to our private cases. Unfortunately it does. Through the courtesy of several gynecologists, I have now seen the husbands in 40 childless marriages. Twenty were actually sterile. Yet the wives of 4 (20%) of these had had more or less severe operations done upon them before it occurred to the operator that perhaps, after all, the husband was at fault.

While these figures are small, we believe them to be representative, not only of this community, but elsewhere. When it is remembered that a man is so often sterile as a result of his own ignorance, and that the innocent wife very frequently falls a victim, should we not be more careful as to where the blame is placed?

Now as to the causes of sterility in the male. While in women nature seems to be responsible in many cases, in man disease plays the chief rôle. In the event of bilateral undescended testicles Belfield (*loc. cit.*) says that no spermatozoa are formed. On the other hand, Simmons and Odiorne (*Annals of Surgery*, December, 1904) and more recently, McGlannan (*Journal American Medical Association*, February 28, 1914) have observed adult spermatozoa and a normal histologic picture in a considerable number of such organs.

In the rare malformations, such as epispadias, certain types of hypospadias, and exstrophy of the bladder, the spermatogenetic function of the testicle may be and generally is unimpaired, but owing to the nature of the defect, coitus is either impossible, or the semen cannot be ejaculated into the vagina.

There are several non-venereal diseases, which, if they attack the testicle or epididymis, may produce sterility in the male. Of these mumps, especially when occurring after puberty, is the most common, with an incidence of orchitis, generally bilateral, estimated at anywhere from 5% (Keyes Genito-Urinary Diseases, 1911) to nearly 33% (Comby, Osler's Modern Medicine). Atrophy of the testis with destruction of its spermatogenetic function follows in a vast majority of these cases.

When we consider that approximately 15% of the adult male population is infected with syphilis and that this may involve the testicle we are at once confronted with another cause of sterility. Syphilis (gumma) of the testicle is fortunately not common, and is generally unilateral. Keyes (*loc. cit.*) records 67 cases, of which only 10 were bilateral. But even if bilateral, the prognosis, after proper anti-syphilitic treatment, is said to be good. Those portions of the testicle which are not sclerosed may functionate and secrete spermatozoa. Gosselin (quoted by Watson and Cunningham) has found spermatozoa in the semen after the cure of this condition. That a restoration to, or a continuance of fertility under these conditions is of doubtful value to the community or to posterity seems to be clear.

The incidence of abscess of the testicle (usually unilateral) in typhoid is only about 2%. The destruction of the organ may be, and usually is, complete.

Tuberculosis of the genital tract, although primary in the epididymis, and even when unilateral, results in azoospermia in about 85%. This catastrophe is to be explained in part by an occlusion of the genital ducts through early involvement of vas deferens, prostate and seminal vesicles. The prognosis is bad, for a considerable experience has shown that, even if early operation removes the diseased epididymis, its fellow becomes involved within a year in more than half the cases.

The abuse of alcohol is also a potent factor in the production of sterility. Simmonds (Keyes, *loc. cit.*) estimates that 61% of all alcoholics are sterile. But in such a condition of narcotism is it not reasonable to suppose that concomitant diseases, generally those of venereal origin, are far more productive of the sterility than is alcohol? Also may not such a loss of the procreative function be desirable under the conditions? Certain experimental evidence, at least, would seem to bear out this conclusion.

Another possible cause of sterility which does not seem to be mentioned elsewhere, is absolute and protracted continence. This statement, made to me by a colleague, is based on the case of a man who was married fifteen years ago. At this time healthy spermatozoa were found in the semen. For reasons best known to themselves the couple have abstained from sexual relations, and there have been no intercurrent diseases. A recent examination of the husband shows azoospermia.

It also seems to be a fact that the otherwise healthy testes of normal, active and sexually vigorous men may occasionally be entirely unproductive of spermatozoa. I have recently been told of such a case occurring in the practise of one of my colleagues, and both Belfield (*loc. cit.*) and Janet (L'Assoc. Franc. d'Urol., 1909, xiii) mention similar examples. The possibility in

such cases of a congenital atresia of the spermatic ducts is not to be disregarded.

Another source of sterility of considerable importance is repeated and prolonged exposure (especially of the genitals) to the Roentgen ray. Those affected therefore, are physicians, x-ray workers, and patients to whom this has been prescribed as a therapeutic measure for other conditions. Brown and Osgood (Trans. American Association Genito-urinary Surgeons, 1907) carefully investigated this question and found, among other things, that (1) spermatozoa themselves are highly resistant to the x-ray, (2) the spermatogenetic cells of the tubules of the testis show degenerative changes, (3) there is no deterioration of sexual activity produced. These investigators also found that in a very small percentage of cases fertility may return after removal of the offending cause.

Infection by the gonococcus is by all odds the most frequent cause of male sterility. From a numerical standpoint all other etiological factors fade into insignificance. The disease is so widespread that statistics collected from various sources place the incidence at from 50 to 75% of the adult male population. It is also well established that prostatitis, generally with more or less involvement of the seminal vesicles, occurs in the vast majority of cases.

The involvement of these organs may result in sterility, a point on which there seems to be general agreement. If the site or severity of the inflammatory process is such as to disturb the patency of the ejaculatory ducts, there will be either azoospermia or oligospermia, depending upon the degree of closure of these structures. When one considers the small calibre of these ducts, their proximity one to the other, and the relation of their orifices to the prostatic urethra, where the inflammatory process is at its height, such an outcome is not to be wondered at. On the other hand, one might well ask why sterility from this cause does not occur with greater frequency. But the procreative capacity of the husband is done away with in prostatitis in another way as well. In such cases there is frequently found asthenospermia, the semen containing a few weakly motile or abnormally shaped spermatozoa, or necrospermia, where these bodies are absolutely motionless, tightly curled on themselves and abnormal in size or shape. These changes are to be accounted for by an alteration in the reaction or composition of the prostatic or vesicular secretion. Just what this change is, or in which organ (prostate or vesicles) it arises, we do not know. But we do know that spermatozoa are killed or inhibited in an acid medium, while they thrive in an alkaline medium. It is probable that in addition to other chemical changes there is sufficient combined or free acid in the secretion of these glands to deprive the spermatozoa of their vitality. Further knowledge, based on scientific, rather than on empirical principles, is much needed before we can discuss this point intelligently.

A fourth complication of gonorrhea following close upon the heels of prostatitis is epididymitis. Its incidence is considerable, Finger (Blenorrhea of the Sexual Organs and Its Complications, Trans. 3rd ed. 1894) reporting 29% in 1844 cases of gonorrhea. While involvement of one side (usually the left) is the rule, the opposite side becomes affected in no small number. In the latter event the percentage of sterility (azoospermia) is exceedingly high. Finger collected 242 such cases from different authors and found azoospermia in 92%. The figures of other authorities, while not so high, give us reason to regard the incidence of sterility in men so affected as 75 or 80%. This unfortunate result is due to occlusion of the genital duct, usually at the lower pole of the epididymis, but often at other points as well. While such a condition would appear to be hopeless, the ingenious operation devised by Martin, of anastomosing the vas deferens to an uninvolved portion of the epididymis, has resulted happily in a large number of cases.

But unilateral epididymitis is not without its drawbacks. Emödi in 31 cases found azoospermia in 9, and the investigations of Benzler (*Arch. f. Derm. u. Syph.*, 1898, xlv) are significant. The latter followed the subsequent history of German soldiers who had had gonorrhea, and who had been married three or more years. Of those without epididymitis 10.5% were childless. Where there had been unilateral epididymitis the percentage rose to 23.4%, while in the bilateral cases sterility obtained in 41.7%. Azoospermia in unilateral epididymitis is to be explained, not alone by a blocking of the genital duct on the opposite side, probably at the prostatic orifice, and without clinical evidence of its occurrence, but also by the prostatitis and vesiculitis which accompanies it.

Finally, gonorrhea may result in sterility by the production of a stricture of the urethra. When its calibre is so decreased as to prevent the free ejaculation of semen into the vagina the results are not difficult to explain. Also it must not be forgotten that behind every stricture there is a more or less well marked prostatitis, and we have seen that this in itself is capable of producing sterility.

I wish now to consider briefly my own experience with sterility in the male, of which, as already stated, I have seen 20 cases. The semen of 10 contained no spermatozoa after one or more examinations One was a case of tuberculosis of the epididymis (unilateral), upon whom I finally operated, but whose initial symptoms had appeared eight years previously; one gave a history of some obscure scrotal swelling (probably mumps) years previously, and with marked atrophy of both testes; in a third, gonorrheal prostatitis and vesiculitis of long duration, and with numerous exacerbations, together with a pronounced atrophy of each testicle of

undetermined cause, was responsible for the condition. In the other 7, bilateral epididymitis of gonorrheal origin was to blame. In all there was also found a well defined prostatitis, the secretion containing much pus.

Six of my cases were found to have oligo- or necrospermia, or both. In 4 of the 6 there was a purulent prostatitis, one associated with an old bilateral epididymitis. The latter, occurring in a middle aged man, in whom no objective or subjective evidence of gonorrhea was found, was undoubtedly due to infection with the colon bacillus, a not infrequent occurrence. The other 3 had been produced by the gonococcus.

The semen of the 2 remaining cases contained only a few immobile and abnormally shaped spermatozoa. Careful examination and inquiry revealed no cause for the condition.

Four more of my series showed a peculiar intermittency in the presence of spermatozoa. None of them had been able to procreate even after years of marriage, and with wives pronounced normal by one of our most eminent gynecologists. At the first, second, and in one or two, the third examination of the semen, no spermatozoa, living or dead, were to be found. On the next occasion the specimen was swarming with myriads of them. Still later, spermatozoa were conspicuous by their complete absence.

One of these was a pronounced alcoholic, but young, and otherwise apparently normal. It seems likely that John Barleycorn furnished the answer.

In another there was a large left varicocele, with marked atrophy of the corresponding testicle.

In the third nothing could be found but a slight degree of prostatitis. In this case the first specimen of semen was sterile, and the second normal.

Lastly, a man with a small spermatocele and a generally cystic feel to the epididymis on the right side. The first sample of semen showed one or two dead spermatozoa. A week later it contained absolutely none. Two weeks later a similarly negative report was given me by Dr. E. L. Keyes, Jr., of New York, to whom I had referred the case. At the end of another week the news came to me that countless active and normally shaped spermatozoa had been found.

Finally, it is of interest that of the four private cases whose wives had already been operated upon, only one was found to produce spermatozoa. In two of the others a bilateral gonorrheal epididymitis excluded all possibility of procreation without previous operation. In the fourth the testicles had been put hopelessly and forever *hors de combat* by an attack of mumps in early manhood.

In closing, it seems worth while to state briefly the method which I have found to be efficient in the examination of such men. A careful history, with special reference to the causes of sterility already mentioned will often give the clue at once. The man's sexual life should also be inquired into. Physical examination involves a rigid routine. The external genitalia are first carefully examined, especially epididymes and testes. Urethral discharge is looked for. The anterior urethra is irrigated with boric acid solution. The patient then urinates in two glasses, that in the first glass showing the condition of his posterior urethra. The urethra is calibrated for stricture. The bladder is filled with boric solution and a rectal examination made to determine the condition of prostate and vesicles. These organs are then gently but firmly massaged. In most cases this serves to express enough secretion to drip from the meatus. Two drops of this are placed on separate slides, one being examined at once for spermatozoa. If numerous and active, the hand of suspicion must then point elsewhere. To the second specimen is added a drop of acetic acid (36%). This is examined for its cell contents, and here the nuclei are so well stained by the acetic acid that one has no difficulty in distinguishing pus from round cells. The presence of pus indicates a prostatitis of greater or less severity. The absence of spermatozoa, however, does not indicate sterility. In the latter event the man is instructed to have intercourse wearing a condom of the thin membrane variety ("beaters skin"). After ejaculation he is instructed to remove this gently from the penis and to place it at once in a wide-mouthed bottle of warm water, keeping its contents from spilling by jamming the open end of the condom between the cork and the bottle. This should be examined at the earliest possible moment after ejaculation, meantime keeping it warm to insure the vitality of the spermatozoa. While haste is advisable, if instructions are carried out, I have found spermatozoa of great activity as long as ten hours after intercourse. If the first specimen is negative, ask for another, and even a third, but be sure that several days or a week of sexual abstinence elapse between. I regard three specimens as the least on which to safely base an opinion.

It will be seen that I have dwelt in this paper upon three points. First, the prevalence of sterile marriage, and the unjust and often unwarranted indictment of the wife; second, the main causes of male sterility have been discussed, and it has been shown that in a great majority of cases venereal disease is the underlying factor; and third, the method of determining the presence or absence of sterility in the male. A fourth point, one of vital importance, dealing with the prognosis and results of treatment in the various conditions enumerated, has been intentionally omitted. It is our purpose to deal with this at greater length in a subsequent communication.

This experience, although brief, is not without its lessons.

1. The cause of sterility in man is due to venereal disease (generally gonorrhea), in the vast majority of cases.

2. Oligospermia or azoöpermia may occur without obvious cause.

3. The production or ejaculation of spermatozoa may be intermittent for reasons as yet unknown.

4. A single examination of the semen is insufficient. At least two, perhaps three or four specimens, each taken after a considerable period of sexual continence, must be seen, before a prognosis can safely be given.

5. Marriage may continue to be sterile even with the finding of active spermatozoa in the husband, and a normal genital tract in the wife. Experience has shown us all that for some reason best known to herself, Nature delays procreation often for years.

6. It is noteworthy that in no case of male sterility regardless of the cause, is masculinity in the least impaired. This is to be explained by the fact that even though the spermatogenetic function of the testicles is inhibited, the internal secretion continues in full force.

STATISTICAL NOTES ON A SERIES OF 6000 WASSERMANN TESTS FOR SYPHILIS PERFORMED IN THE HARVARD NEUROPATHOLOGICAL TESTING LABORATORY, 1913.

BY E. E. SOUTHARD, M.D., BOSTON,

Bullard Professor of Neuropathology, Harvard Medical School; Pathologist, State Board of Insanity, Massachusetts; and Director, Psychopathic Department of Boston State Hospital, Boston, Mass.

THE value of the present series of Wassermann tests is enhanced by the interest which the laboratory officers have taken in the clinical diagnoses of the cases tested and by the courtesy with which the clinicians submitting specimens have given important data.

Since the Harvard Neuropathological Testing Laboratory is not a commercial institution and has performed much charity work in addition to its other work (paid for virtually at cost), a spirit of cooperation has grown up which has helped in the solution of many problems of individual diagnoses.

The Testing Laboratory, of which the last year of work is here summarized, was, I believe, the first to be established in Massachusetts to make use of the ingenious discovery of Wassermann, and, since it has been in continuous action under its various heads, (1) Professor F. P. Gay (now of the University of California) who established the standards since maintained, (2) the late Dr. Emma W. D. Mooers, who brought to the work a great interest in both the technique and the clinical significance of the tests, derived from her work with Plaut in Munich, (3) Professor W. P. Lucas, (now of the University of California) who turned his attention to numerous clinical problems, not only of children, but in general, and (4) their successors (see below), the Laboratory has had a very varied experience and has sustained most of the shocks which the numerous pitfalls of the test provide. The result has been an increasing confidence in the tests as made, and fewer and fewer complaints of lack of congruence between the results of the tests and clinical findings, especially when these latter are reviewed.

My own interest in the tests was in the first instance psychiatric and neuropathological, and I believe that the laboratory would hardly have survived, had it not been for the interest in these tests taken by the state institutions for the insane. The work published heretofore, based on this laboratory's tests, has been largely psychiatric, as the following titles illustrate:

Lucas, W. P. The Wassermann Reaction in its Application to Medicine. BOSTON MEDICAL AND SURGICAL JOURNAL, clxix, 1913, No. 4, pp. 116-121, July 24, 1913.

Paine, H. L. Results of the Wassermann Test in Two Hundred Consecutive Admissions to the Danvers State Hospital. BOSTON MEDICAL AND SURGICAL JOURNAL, clxviii, No. 14, pp. 501-503, April 3, 1913.

Morse, M. E. Correlations of Cerebrospinal Fluid Examinations with Psychiatric Diagnoses: A study of 140 Cases. BOSTON MEDICAL AND SURGICAL JOURNAL (in press) Worcester State Hospital Contributions No. 20, 1914.1.

I believe the value of the Wassermann reaction will always remain even more critical in the neurological arts than in those of the syphilographer who has so many more clinical data immediately accessible to him. It is to be hoped that some state agency will take over the entire task of Wassermann-testing on a scale commensurate with its value. If so, it is the experience of the present Laboratory, which has been virtually supported by cooperation of several of the larger hospitals for the insane, that psychiatric and neurological cases will absorb the lion's share of attention, although from time to time many series of sera will be submitted by physicians having special therapeutic tests (salvarsan, neosalvarsan) in hand.

There are Wassermann tests and Wassermann tests! In comparing our results with others, we often find tests described as Wassermann tests which are somewhat essentially different therefrom. Needless to say some workers omit various precautions and controls which are essential to reliable work. To make clear the policy of this laboratory, which has been managed in common by the writer, by Professor H. M. Adler, and by Dr. Annie E. Taft under the Department of Diseases of the Nervous System of the Harvard Medical School, I propose to set down (without description) the steps, precautions, and controls used in the series of tests, which are now being executed by Dr. W. A. Hinton.

(A.) *Materials*:

(1) washed sheep corpuscles, 5% suspension, 5 c.c. to tube.

(2) antisheep amboceptor, 2 units.

(3) complement (guinea-pig serum, 10%), 2 units.

(4) patient's serum inactivated at 56,° 0.1 c.c. with each antigen.

(5) antigens (a) human heart reinforced with cholesterin (0.1 c.c.)

(b) human heart reinforced with cholesterin (0.05 c.c.)

(c) alcoholic extract of syphilitic fetal liver (0.25 c.c.)

(B.) *Controls*:

(1) antisheep amboceptor unit tested daily.

(2) Compliment unit tested daily.

(3) 0.2 c.c. inactivated patient's serum used in addition to test with 0.1 c.c.

(4) each specimen tested with three antigens.

(5) control to exclude the (rare) occurrence of natural hemolytic power in complement.

(6) same hemolytic power in amboceptor.

(7) same, salt solution.

(8) control sera six in number (strong positive, slight positive, negative; each antigen doubled in amount.)

(C.) *Remarks*:

(1) period for fixing complements, 1 hour.

(2) doubtful cases repeated with double amount of serum and appropriate controls.

(3) cerebrospinal fluids used in five times the amount of sera.

(4) attention may be called to the "slight positive control (v. B., 8 above) which prevents many slightly positive cases from being overlooked on a given day.

(5) attention is especially called to the use of *three* antigens (This is not usual in many American laboratories), excluding technical error, perhaps indicating slight quantitative changes in a given patient's reaction, and excluding certain false positions.

(6) supervision and control, (highly important where so important a diagnosis as syphilis is being rendered) are obtained by the direct contact of (a) secretary, (b) technician, (c) laboratory boy, in addition to medical expert diagnostician (during 1913, Dr. W. A. Hinton) under general direction of Dr. Annie E. Taft, Custodian, Neuropathological Laboratory, Department of Neuropathology.

GENERAL STATISTICS.

Total Wassermann tests, 1913		6139
Blood sera	5282	
Cerebrospinal Fluids	857	
Total tests repeated		228
Blood sera	186	
Cerebrospinal Fluid	42	
Total individual blood sera		5096
Cerebrospinal Fluids	815	

An important question is always raised by tests which have to be classed as doubtful in result. These doubtful tests occupy a large share of attention and inspire requests for new specimens. I was surprised to learn the low percentage of such doubtful results when all the tests were summed up. The percentage (2-4%) is somewhat like what might be expected of a biological test. The fact that there are more such doubtful tests in sera than in cerebrospinal fluids signifies doubtless the larger number of confusing substances in the blood as well as other technical difficulties. The figures follow:

Total blood sera	5282
"Doubtful" results (4%)	202
Total cerebrospinal fluid	857
"Doubtful" results (2%)	19

It may be properly inquired what is the result of repeated tests in connection with these "doubtful" cases. The following table demonstrates cases in which a change in result was registered involving "doubtful" tests in sera:

"Doubtful" became negative	17
Negatives became "doubtful"	4
"Doubtfuls" became positive	2
Positives became "doubtful"	5

This table would incline one on statisical grounds to prefer to call "doubtfuls" negative. Suppose we look at a group of non-"doubtful" cases to see how they turn with repeated tests.

Negative cases become positive (of which 3 had also been postive also before the initial negative and one had been "doubtful.)"	15
Positive cases become negative (of which three became positive again later and one had been negative before the initial positive.)	33

If we leave out the anomalous examples of one dissimilar test in a triad, we arrive at

Negative cases become positive	11
Positive cases become negative	29

Comparing this with data above:

"Doubtfuls" become positive	2
"Doubtfuls" become negative	17

we see that, statistically at least, "doubtfuls" resemble negatives more than positives. This also confirms the qualitative suspicions of many workers. Nevertheless it must be pointed out that this general trend toward negative is partly due to natural immunizing or spirochaete-destroying factors at work in the individual and partly to therapeutic efforts.

The figures with respect to "doubtfuls" and changes of reaction in cerebrospinal fluid are as yet too small to make tabulation profitable.

If we exclude "doubtful" tests and limit consideration to the positive and negative tests alone, we have the following denominators:

Blood sera	5096
Cerebrospinal fluids	815

Concerning these blood sera in our laboratory it is not at all certain that they represent the community fairly; indeed it is highly probable that they are a picked class of sera derived from patients in whom syphilis was seriously suspected.

Positive blood sera (23%)	1161

And it is certain that the cerebrospinal fluids are a still more highly selected class

Positive cerebrospinal fluids (33%)	267

It is an interesting speculation to consider how far this 33% of positive cerebrospinal fluids represents the chance that an "organic" disease of the nervous system has of being syphilitic.

From the community's point of view it is clear that the percentage of outstanding syphilis is not so high as alarmists have sometimes thought. It is probable from such data as these that the percentage of syphilis in the community is far below 23%.

A curious fact is illustrated by the figures from the Worcester State Asylum, a transfer institution for chronic patients. This institution harbors syphilitics (3 in 103) not quite to the extent of 3% (2.9%.) Here is a community from which the luetic organic cases have largely never been sent. The chances are that this percentage is lower than that of the community at large.

On the other hand, if we consider the girls of the Massachusetts Reformatory for Women, we find the extraordinary percentage of 44, that is, 112 positives in 254 cases.

Some facts concerning the Psychopathic Hospital data were worked up more particularly for the benefit of the White Slave Commission, and the following paragraphs are reproduced from a report to Dr. Walter E. Fernald, Chairman of that commission.

"I. The general average for the whole state of cases thought by the hospital physicians to be due to syphilis is 5.49% for the three years 1910-1912, and 6.28% for the year 1912 itself. This figure can be safely stated to be far too low because the average percentage of general paresis during the same three years (1910-1912) was 8.43% (for 1912, 8.65%.) This latter figure is also beyond question too small since a certain proportion of coarse brain lesions of epileptic insanities and of imbecilities are undoubtedly due to syphilis, although they are classified outside the syphilis group in the figure presented by the Board of Insanity from which I make the above extracts.

"II. The best information available to me as to the general percentage of syphilis to be found in mental cases is that afforded by our experience at the Psychopathic Hospital covering 1671 separate random tests on different persons. 264 of these 1671 persons were determined to show syphilis so far as the Wassermann reaction carried out under the precepts of the original method can be trusted. I consider that there is no better set of data available for Massachusetts. This will be found to work out a percentage of 14.7% for our Psychopathic Hospital intake. I think our Psychopathic Hospital intake may be regarded as more representative of the general population than any admissions in previous years to other insane hospitals. An indication of this for example, is the fact that we discharged 250 persons during the last year alone as "Not Insane" although every one of these cases presented some kind of mental problem. It is rather curious that the percentages which we here work out, viz., approximately 15%, correspond to the idea prevalent I believe among dermatologists as to the general percentage in the community which they deduced from cases resorting to skin clinics.

"III. In a series of random "organic" cases 321 in number, I found cerebrospinal fluids positive in 118 cases or about 37%. You will of course wonder how I determine cases to be "organic." My general policy has been to have examination of the blood serum made in all cases having severe mental symptoms. If the serum is positive, I proceed as a rule to an examination of the cerebrospinal fluid by the Wassermann and other methods, believing it to be of importance to determine whether a case is one of General Paresis or of some other form of cerebrospinal syphilis. In case the serum is negative but the patient shows signs of disorder in the projection system, or as we say, looks "organic," then I proceed to a cerebrospinal fluid examination, despite the negativity of the serum. It is from these two groups that my random organic series of 321 cases is made up."

Following is not intended as a complete account of the Wassermann technique but only to record the particular materials and main steps used in this laboratory in 1913, so that it may be known exactly what we mean by "Wassermann" tests.

SUMMARY.

1. On account of the varying standards and criteria which have held or will in future hold in the matter of Wassermann tests for syphilis, it has been thought wise to summarize the materials, controls, and special precautions used in the Harvard Testing Laboratory.

2. General doubts are often raised as to the reliability of Wassermann's test on account of the "great number" of "doubtful" reactions; this "great number" resolves in our large series to 4% of the blood sera and 2% of the cerebrospinal fluids.

3. On statistical grounds we find the "doubtfuls" resolve much more frequently into "negatives" than into "positives."

4. 23% of all sera examined were positive, and since the cases are in many instances picked as likely to be positive, this percentage is doubtless much higher than the community's total percentage.

5. 33% of all cerebrospinal fluids examined were positive. The principle of selection of these cases was such (positive serum or symptoms of "organic" nervous or mental disease) that the result is of practical value, stateable as follows: The chances of a syphilitic origin for a case of "organic-looking" nervous or mental disease are not more than one in three.

6. The Massachusetts Reformatory for Women yields 44%, a partial index of the infected nature, though not necessarily of the infectivity, of prostitutes and other delinquent women.

7. The Danvers State Hospital (for the insane) yields between 19 and 22% positive sera in its routine intake of cases from Essex County.

8. The Worcester Asylum, a transfer institution (to which are transferred chiefly *non*-paretic cases), yield less than 3% positive. If this percentage should be maintained in future work, one might infer that, from the group of persons in the community with insane tendencies and infected by syphilis, cases are drained off into the frankly paretic group, in such wise that a population of asylum *transfers* will be likely to show a *low* syphilis index. But this conclusion can be only tentative on account of many other issues.

9. The Psychopathic Hospital index (15%) is perhaps somewhat closer to the general community index than the others just mentioned on account of the large number of cases "not insane" that are tested, but it is evident that 15% would be too high an index to assign to the syphilis of the general population.

10. Aside from its capacity to solve problems of individual diagnosis, the Wassermann method is obviously of such value to the community that a community Wassermann service might well be undertaken by a state agency such as the Board of Insanity or the Board of Health.

CYSTITIS—AN INCOMPLETE DIAGNOSIS.*

BY BENJAMIN TENNEY, M.D., BOSTON.

Surgeon to the Boston Dispensary.

THE number of proprietary and semi-proprietary remedies for "cystitis," "catarrh of the bladder," "inflammation of the bladder" which are advertised to the profession and to the public is equalled only by those for "indigestion," "dyspepsia," and "rheumatism." This can mean but one of two things, either the profession fails to make a complete diagnosis followed by curative treatment or else the condition leading to the symptoms is either extremely resistant to treatment or incurable.

People in pain and with physical handicaps go to some doctor at some stage in their disease as a rule. If they are then told what they already know and given some treatment from which they obtain but little relief, they try other men or clinics until they are relieved or they class all medical help as futile and turn to proprietary medicines or extra-medical delusions. It has been said before that the list of remedies for a given disease was a fair indication of our uncertainty in the treatment of the disease, and it may be said with equal truth that the number of proprietaries and semi-proprietaries advertised as cures corresponds somewhat with the failure of the general profession to promptly and permanently relieve the pains and other handicaps of people who are not well.

Some things are still beyond prompt or permanent relief, but more human ails are controllable now than ever before and a large part of our gain has come from perfecting our diagnosis. A completed diagnosis based on findings apart from the patients' statements and not inconsistent with the statements leads to a choice between a small number of therapeutic measures —often to a choice between mechanical treatment or none.

An incomplete diagnosis leads nowhere, but leaves both doctor and patient in a fog of uncertain and changing therapeutics until nature kills or cures.

To return to the title of this paper, the diagnosis of cystitis is made on one or more of the following symptoms and signs.

1. Frequency of urinating.
2. Pain in connection with urinating.
3. Pus, red corpuscles, and shreds in the urine.
4. Tenderness of bladder to pressure.
5. Appearance through cystoscope.

Three of these can be studied apart from the patient's statements.

1. Frequency in urination depends on the distensible capacity of the bladder quite as much as on the rate of kidney excretion. In urinary tuberculosis and some stages of urethral ob-

* Read before the Somerville Medical Society, May 7, 1914.

struction the actual capacity of the bladder may be reduced to an ounce or less. If the bladder with prostatic or stricture obstruction holds sixteen ounces and always has a residual of twelve ounces its distensible capacity is only four ounces, and as soon as the kidneys have secreted four ounces of urine it calls for relief. If a bladder is in spasm from ureteral irritation its distensible capacity may be a few drachms for some hours and then return to normal. We read and hear of "irritating" urine, and "too acid urine." Both may exist, I do not know, but I have yet to find the patient whose bladder will hold much more warm boric solution than it did of the urine previously expelled from his full bladder.

The common experience of us all in health is that in cold weather with little or no perspiration and dilute urine we empty our bladders more frequently than in hot weather with free perspiration and concentrated urine, unless we make up for perspiration by extra drinking of fluids. The experience of travellers in the desert and of sailors and others deprived of drinking water for long periods indicates that the concentration of the urine has little or no effect in increasing the frequency of urination. On the other hand, most of us know that apprehension or fright will increase the frequency more than can be accounted for by increased kidney secretion. Here the distensible capacity of the bladder is diminished for the time, but returns to normal when the excitement is over.

The distensible capacity of the bladder in health is not absolutely constant owing to the central nervous disturbances. It is also altered in certain cord lesions and in diseases which affect consciousness.

Apart from these extra vesical influences each individual has a normal capacity of his own, which in health will determine the frequency of his urination. In general one whose comfortable distensible capacity is sixteen ounces will have no night urine unless he takes a quantity of fluid during the evening, while one with less or with the habit of evening drinking will probably urinate during the seven or eight hours reserved for sleep. Any condition that diminishes this distensible capacity of the bladder will increase the frequency. External tumors will do it while the bladder remains healthy. Internal tumors by obstructing the urethra and causing hypertrophy of the bladder wall, by their own bulk and perhaps by irritation of the cord centre, will accomplish the same result. Foreign bodies in the bladder may act in precisely the same way. Ulcers of the bladder mucosa probably act on the cord centre only.

My observation has been that any process either above or below the bladder which disturbs the muscle bundles, which are continuous with the longitudinal fibres of the ureter, is associated with the desire to urinate. There is a point just below the internal meatus, where the muscle bundles from the left and right ureters meet and the touch of a sound here brings on the desire to urinate. Inflammation and growths at this point produce the same sensation. This must be a reflex from the cord centre corresponding to the natural impulse to urinate, which is said to be due to the upward pull of the distended bladder on these same muscle bundles. If this be true then any condition pulling on this area will probably cause the same sensation and a hypertrophied ureter wrestling with a calculus, or inflamed by extension of a pyelitis or tied down by adherent appendix or dragged upon by a prolapsed uterus may give the sensation. We find all these conditions accompanied by frequent urination.

Another type of frequent urination is seen in patients who have a weak sphincter and accustom themselves to the habit to avoid the annoyance of incontinence. This is not uncommon in women who have some injury to the urethra during childbirth. Frequency in urination is a poor reason for the diagnosis of "cystitis" without eliminating these other causes for the same symptom.

2. Pain with urination may precede, accompany or follow the act. Preceding the flow it indicates that the distensible capacity of the bladder has been exceeded. Pain during the flow indicates that some inflamed area is being altered in its relations, pulled upon, compressed, or dilated. Pain after the flow is often due to a spasm or cramp of the bladder wall as it responds to an over-stimulus for contraction and any severe inflammatory condition within the bladder wall or the first part of the urethra or the lower portion of the ureter may cause this.

The diagnosis of cystitis from the symptom of pain is not fair to the patient until the possibly serious conditions above, within and below the bladder have been eliminated.

3. Pus, red corpuscles, and shreds in the urine must be seen in catheter specimens from a female and in "second glass" specimens from a male to be considered in this diagnosis. In such specimens the presence of pus and blood indicates trouble, but has no localizing significance, as the source may be in either kidney, either ureter, or the bladder. Shreds showing papillomatous arrangement suggest bladder growths, but tumor cells may sometimes be identified with no clue to their exact source. Pyuria and hematuria are the cardinal symptoms in new growths, lithiasis, and destructive infections of the kidneys and ureters, and a diagnosis of cystitis in the presence of such findings without careful elimination of these dangerous conditions is unfair to the patient and unwise of the doctor from every point of view.

4. Tenderness to pressure in the region of the bladder is misleading. In the male it is confused with tenderness of the seminal vesicles and prostate. In the female, tenderness of the ureteral insertion is a well known indication of inflammatory condition higher up on the same side. Tenderness of infected Skene's glands

may be confused with bladder tenderness as may the inflammatory conditions in and about the broad ligament. Tumor and stone are often causes of exquisite tenderness. The over-distended bladder may be sensitive, but after relief is usually free of all reaction to pressure. As a leading symptom of cystitis it is seldom mentioned and as a confirmatory symptom it is almost worthless.

5. The appearance through a cystoscope is the only finding upon which a diagnosis of cystitis can be made, and the more cases one observes through this instrument the more rarely does one make the diagnosis of cystitis without some really anatomical cause. Red, thickened, bleeding bladder mucosa is sometimes seen, but with these findings we find urethral obstruction, or bladder tumors, ulcers, foreign bodies, diverticula and distorted ureteral orifices, or we search further with ureteral catheter and x-ray until the disease which produces the symptom—cystitis—is found.

We all know that there are many individuals who have these conventional symptoms of cystitis at some time, and others who have recurring attacks. We know, too, that tuberculosis and other destructive infections above and below the bladder, stones, and tumors of the most serious nature first make their presence known through these same symptoms, which are often intermittent. If such a case is seen when symptoms are active and the diagnosis of cystitis is made, the decline of symptoms may be credited to the last drug given, when it is merely what may be called the "negative phase" of the disease. Neither patient nor physician is wiser as a result of the experience, but both are deceived.

The diagnosis of cystitis deserves a place in medicine with "peritonitis," "rheumatism," "gastritis," "neuralgia," and many others which have been resolved into their proper component parts. The sooner we banish it from our own and our patients' vocabularies, the sooner will we make complete diagnoses and deal fairly and honestly by our patients, and the sooner shall we close another avenue through which the patent medicine man gains at the expense of our imperfectly treated, because imperfectly diagnosed patients.

It is easy to cite cases to illustrate the unnecessary suffering and finally crippled condition into which some victims of this diagnosis fall. The most unfortunate have been those with tuberculosis of the kidney.

One such, a man of 32 came in July, 1909, with a story of "inflammation of the bladder" for two years. He had been dosed, his bladder had been washed, he had taken gallons of water and had even spent six weeks in bed with a cystotomy wound to relieve his cystitis. While he made a good recovery from his nephrectomy and has gained thirty-five pounds in weight, his bladder is so contracted by the constant irritation through the inflamed ureter that it is doubtful if he ever recovers a comfortable capacity or normal intervals of urination.

A second was an Italian of 36 who had spent all his savings on pills and potions and local treatment for a period of five years. He was wasted with pain and lack of sleep and had been in bed a month. In the course of his search for health he had had a testicle removed for tuberculosis. A nephrectomy relieved him of most of his pain, he gained forty pounds in weight, worked for nearly a year and then died of some other disease.

A third was an active business man of 38 whose symptoms had existed for two years. Among all the medical men he consulted, one only had told him he had a tubercular kidney and he had seen many and those of good standing. All others told him he had chronic cystitis and treated him therefor. He recovered from his nephrectomy, and lived some months in comparative comfort, though his wound broke down and he had reflux urine through the ureter stump. A reasonably early diagnosis and nephrectomy would have made him an active man for years, to say nothing of the suffering he would have saved.

A fourth was a woman of 35 who had been from one physician to another and then to hospital for pelvic surgery to relieve her right-sided pain and cystitis during a period of three years. A completely destroyed kidney was removed six years ago and today her bladder will hold twelve ounces of fluid and she often sleeps the night through, instead of rising every half hour.

A fifth gave a history of cystitis in 1906, lasting about two weeks and cured by buchu, a recurrence in 1908 cured by tablets, in the meantime a pelvic operation and "cystitis from catheterization" during her convalescence. A left tubercular kidney was removed in 1910 with immediate relief of her pain and gradual return of her bladder to normal function.

Almost every patient with tubercular kidney gets a diagnosis of inflammation of the bladder unless he happens to consult a urologist first, and yet if there is any disease besides cancer where early recognition and treatment is the patient's surest way to avoid suffering, that disease is tuberculosis of the kidney.

Of the cases of stone and cystitis, the most striking among my patients was a woman of 72. Pain and frequent urination amounting to incontinence had been her portion for forty years. I do not know what diagnosis her physician made, but he fitted a leather covered metal plate, eight inches in diameter, held by straps about her body to press on her lower abdomen. This she had worn faithfully and hardly stepped off her piazza for the last twelve years. An observing nurse called my attention to her urinary frequency and a glass catheter made the diagnosis as a specimen of bladder urine was being drawn. With the stone removed her life has been transformed, but the bladder will never get back to the normal capacity. Her relief came too late.

Patients with urethral obstruction whether from stricture or hypertrophied prostate, form another group that suffers from the diagnosis of "cystitis." Most have the symptoms, but they are in worse case than patients with "neuralgia" from an ulcerated tooth, "gastritis" from a gall stone, "rheumatism" from a dislocated semi-lunar cartilage, and "peritonitis" from a perforation in the intestines because there is no hope of spontaneous relief, which may possibly, though it does rarely, occur with these other conditions.

To give cases illustrating the common delay in proper diagnosis and treatment of these conditions one has only to turn to his records of prostatic enucleations and operation for stricture. They vary only in the length of time the patients have suffered waiting for a complete diagnosis. These details are unnecessary and within the personal knowledge of almost every practitioner, and the diagnosis of urethral obstruction is so easily made that any delay in reaching it seems inexcusable.

Patients with new growths in the kidney and bladder form the most important, though the smallest, group of sufferers through the diagnosis of cystitis. If any relief is possible for these patients, diagnosis must be made early and treatment promptly applied. A few months may make the difference between a hopeful and a hopeless case.

Fortunately there is a growing appreciation of the seriousness of frequent urination, painful urination, hematuria, pyuria, and the other urinary symptoms, both within and outside the medical profession. Patients are demanding permanent relief from their pains and disabilities, and physicians are fast giving up the old theoretical pathology, which was made to fit the symptoms, for the modern pathology of the living.

A STUDY OF EXTRA-PULMONARY AND OTHER SOUNDS WHICH MAY LEAD TO ERRORS IN THE DIAGNOSIS OF PULMONARY TUBERCULOSIS.

By John B. Hawes, 2d, M.D., Boston.

[From the West Medical Service of the Massachusetts General Hospital.]

In this paper I shall discuss certain sounds, not due to tuberculosis or any pulmonary disease, but to physiological processes, which sometimes lead to confusion in the diagnosis of pulmonary tuberculosis. These sounds may cause errors in diagnosis, either by simulating râles or else by obscuring the breath sounds or such râles or other abnormalities as may be present. The conclusions which I have reached in this matter are based on a study of 250 patients seen during the past eighteen months in private practice and in my clinic at the Massachusetts General Hospital. There has been no selection of cases although the greater number were patients in whom pulmonary tuberculosis was present or suspected. I have undertaken this work not to investigate in detail the exact nature and cause of these sounds and the various conflicting theories concerning them, but to find out as far as possible how large a factor, to the general practitioner, such sounds may be in making his diagnosis of chest conditions and, of special importance, how errors due to such causes may be avoided. The sounds here considered are as follows:

1. Muscle sounds.
2. Joint sounds.
3. Tendon or bursal sounds.
4. Atelectatic râles or crackles, otherwise known as marginal sounds.

Muscle Sounds. A detailed description of muscle sounds is unnecessary. In any text-book on physical examination or diagnosis a full description of their nature and origin will be found. In brief, muscle sounds may take the form of a low pitched rumble or roar so loud as to obliterate all breath sounds, or else they may be heard only at the end of forced inspiration. Occasionally they closely resemble a shower of dry crackles.

Joint Sounds. These sounds, to me at least, are more interesting and important and more frequently lead to errors in diagnosis than any of the others. My attention was first called to them by an article by William Ewart[1] of London, to which the reader is referred. In this paper Ewart discusses in detail the original work of Perez and the sign bearing his name besides giving complete bibliography on this subject. Perez was apparently the first to note that certain sounds are produced in joint movements, which in the case of the shoulder and sternal joints may closely resemble râles and may thus lead to errors in diagnosis. "Perez's sign consists essentially in the production of sounds over the upper thoracic surface on actively or passively moving the arms at the shoulder joint, and particularly by raising or lowering them."[2] In a certain small proportion of cases, particularly among those who raise their shoulders up and down in breathing, enough of such joint sounds are produced in the movements of the acromio-clavicular, sterno-clavicular joints and elswhere to cause confusion.

Tendon or Bursal Sounds. These are best described by an article by F. T. Lord.[3] His is the only detailed description of such sounds and how they are produced that I have found. As I shall later point out, I have not found them to be the cause of any confusion.

Atelectatic Râles or Crackles. These sounds constitute a well-known and common phenomenon, but should only rarely lead to errors in

diagnosis. I have included so-called marginal sounds in this group. Although there seems to be considerable difference of opinion as to this I cannot consider marginal sounds as due to anything but the expansion of an atelectatic area in the lung. Bushnell[4] discusses this point at great length, and although he does not commit himself definitely, he seems to feel that such sounds are due to a physiological but not a pathological atelectasis. For the more detailed discussion of these points, and for many others bearing on the subject of extra-pulmonary sounds, the reader is referred to Bushnell's most excellent and comprehensive article.

Of my series of 250 patients, there were 133 males and 117 females. There were 16 children, 15 years old or under, 211 whose ages vary from 16 to 45 years and 23 over 45 years of age. In 169 cases the lungs were normal, 67 had pulmonary tuberculosis more or less marked, 3 a tuberculous pleurisy, 4 acute and 6 chronic bronchitis, 1 chronic influenza. As to the type of patient I have more or less arbitrarily divided these cases into groups, as follows:

1. Fat .....48 cases
2. Fat and muscular .....28 cases
3. Thin .....69 cases
4. Thin and muscular .....33 cases
5. Muscular .....61 cases
6. Emaciated .....11 cases

MUSCLE SOUNDS.

In discussing this subject and others I shall use the terms "absent," "slight," or "marked" in a relative and not an absolute sense. In every individual muscle sounds of greater or less degree can be heard on careful listening; when they are classed as "absent" it is meant that they are negligible as a factor in causing confusion or errors in diagnosis; the same applies to the term "slight" or "marked," not only as regards muscle sounds, but as to joint and bursal sounds and atelectatic râles. In this series of 250 cases muscle sounds, as a factor in causing mistakes, were "slight" in 25 cases, "absent" in 168 cases,—a total of 193,—and "marked" in 57 cases. Of the 193 patients in whom such sounds were absent or slight, 107 were males and 86 females. Of the 57 patients in whom I designated muscle sounds as "marked," 49 were males and 8 females All of these 57 patients were in the "muscular" group, "fat" or "thin," as the case might be. In 23 of the 57 cases, or in 9.2% of the whole number, the muscle sounds either closely resembled râles or else markedly interfered with breath sounds or the detection of other abnormal conditions. Among the 16 children, 15 years old or under, there were two instances where muscle sounds were a potential source of error by obscuring other sounds.

JOINT SOUNDS.

Joint sounds, loud enough to be distinctly audible on auscultation of the apices, front or back, were present in 126 cases. They are easily elicited by rotating the arms or by moving them up and down with the stethoscope held over the apex, front or back, or over the upper part of the sternum. Of the 126 patients in which such sounds were present, 75 were males and 51 females; joint sounds were slight in 83 and absent in 41 instances. Of this last group in which no joint sounds were heard, 17 were males and 24 females. On quiet normal breathing joint sounds were heard in only 9 cases, while there were 55 patients, or 22% of the whole number, in whom joint sounds were present on more forcible breathing and in whom they either closely resembled râles or in other ways led to confusion. In most instances, I have described these sounds as "too loud and coarse," "too snappy," "too harsh," "too metallic and near the ear" to be mistaken for râles. There were no joint sounds heard in examining the 16 children in the series.

TENDON OR BURSAL SOUNDS.

On listening in the scapular region as a part of a regular routine in each of these 250 cases I heard what I believed to be tendon or bursal sounds in 10 instances. These I have described as loud "snaps" or "clicks"; they did not resemble râles in the slightest nor could they be considered in any way a cause of error in diagnosis. In 7 cases they were found in muscular males; 1 case occurred in a very emaciated man, and two in fat women.

ATELECTATIC RÂLES.

I do not consider that this is the place to enter into a detailed discussion of the relation of "marginal sounds" to atelectatic rales. For this, as above mentioned, the reader is referred to Bushnell's[4] article. I think it safe to assume that both, doubtless for different reasons, are due to the sudden opening of pulmonary aveoli which were previously closed. Cabot, Bushnell, and others are on record as finding such sounds or râles in an amazingly large proportion of healthy individuals. For my own part, I was strongly of the opinion, previous to this investigation, that I could find râles at the bases posteriorly in the lungs of 80% to 90% of fat women not suffering from any pulmonary disease. It may be purely a coincidence that in this series of 250 individuals, 48 of whom I have classed as "fat" I could hear such atelectatic râles in only 5 instances. These 5 consisted of 3 women and 2 men, all in the "fat" group. As to the râles or marginal sounds heard in the lungs of healthy muscular persons, especially men, as described by Bushnell, I could find no evidence.

IMPORTANCE OF THESE SOUNDS TO THE GENERAL PRACTITIONER.

It seems to me safe to draw the following conclusions as a result of this investigation concerning these various sounds and their importance to the general practitioner in making lung examinations:—

First as to *Muscle Sounds*. In this particular series they appeared to me to be a potential cause of error in 9.2% of the cases. It was particularly in muscular, closely-knit young adults that they were most marked. The temperament of the patient, whether nervous or otherwise, seemed to play a part, those patients manifestly nervous on being examined presenting louder sounds than those of the phlegmatic type. This factor, however, did not seem to play so large a part as that of the patient's actual musculature. In the great majority of instances the muscle sounds took the form of a low roar, obscuring all other sounds; only rarely did they resemble râles.

Next, considering *Joint Sounds*, I found here a larger source of confusion than muscle sounds. In 55 instances, or 22% of the whole, sounds were present on forced breathing, which closely resembled râles. Sex seemed to make no difference in the occurrence of this phenomenon, nor did the patient's age except that no case occurred in the children in the series. Likewise, the physique of the patient did not seem to be a factor. As would naturally be the case, it was in patients who used the accessory muscles of respiration in breathing that the joint sounds were most marked. It is evident, to me at least, that joint sounds deserve careful consideration as a possible cause of error in diagnosing pulmonary disorders.

Tendon or Bursal Sounds do not resemble nor obscure râles or breath sounds, nor do they occur often enough to be seriously considered.

Atelectatic Rales or *Marginal Sounds* ought never to be a source of error. The latter, as described by Bushnell, I have not been able to find, and the former are usually self-evident and rarely simulate râles due to a tuberculous process.

HOW TO AVOID ERRORS DUE TO MUSCLE OR JOINT SOUNDS.

Muscle Sounds often make diagnosis very difficult. Such sounds, in very muscular and nervously wrought-up persons may render it absolutely impossible to come to any accurate conclusions as to râles or breath sounds. In such cases every effort must be made to make the patient relax physically and mentally. Too cold an examining room or too light a wrap over the patient may be important causes of such sounds. In every instance intense concentration on the part of the physician is necessary.

The avoidance of errors due to *Joint Sounds* is an easier matter. I have made it a part of my routine examinations as a result of this study, whenever joint sounds or sounds simulating râles which I think may be joint sounds, are present, to put the patient through the following procedure: The patient closes his nostrils tightly by holding the nose, the mouth is shut, so that no air can get in or out of the chest, thereby doing away with all movement of air in the lungs; and the patient is then told to "go through the motions of taking a full breath without taking one." Usually the patient is quite at a loss as to what to do; a few minutes instructions on my part, however, with an explanation of what I am aiming to accomplish, has in every case made everything perfectly clear and easy. As in doing this there is no movement of air inside the lungs, there can be no râles. In many cases, when for some reason I have been suspicious of a shower of crackles unexpectedly heard at one apex after a deep breath, I have made the patient go through this procedure and have heard the identical shower of crackles as before. This is conclusive proof that such sounds are surely not râles and that in all probability they are "motor joint crackles." It is needless to mention the importance of such a decision as this to the physician in making his diagnosis and to the patient as to prognosis and treatment. I have not found that this simple procedure has been previously described. In my own work I have found it of value. I believe that it will be so to others.

Finally, I would briefly summarize this study as follows:—

1 *Muscle Sounds* were a potential source of error in 9.2% of the 250 cases. Such sounds occur, particularly in muscular persons of nervous temperament. These sounds can be lessened by quieting and calming the patient and by seeing the the examining room is sufficiently warm. Errors due to these sounds can be avoided only by great care and concentration on the part of the physician.

2. *Join. Sounds*, resembling râles and a potential source of error, occurred in 22% of this series. Errors due to this cause may be avoided by the procedure described in detail above, of making the patient "go through the motions of breathing without taking a breath." This should be done in every doubtful case.

3. *Tendon or Bursal Sounds, Atelectatic Râles or Marginal Sounds*, ought not to cause confusion or be sources of any mistakes in diagnosis.

A PLEA FOR EARLY OPERATION FOR GALL STONES BASED ON AUTOPSY RECORDS.

BY J. C. HUBBARD, M.D., BOSTON,

Assistant Surgeon, Boston City Hospital; Associate in Surgery, Harvard Medical School.

Not long ago cholelithiasis was considered a disease for medical treatment, and the patient's life was regulated accordingly. Gradually it became evident that surgery could offer a better outlook to the average patient suffering from gall stones than medicine. Recently I reviewed the autopsies, where gall stones were found, made at the Boston City Hospital. When my work was done and the figures put together, I was surprised to see what an unrefutable argument they offered for early operation. The number of cases is not large but the evidence is conclusive. The cases include all in whom a gall stone was found at autopsy.

The presence of gall stones was suspected in some and unrecognized in others. They include cases from the various departments of the hospital. A very few follow an operation, but only such of those are included here as had stone at autopsy. It seemed fair to include these, an exceeding small number, for the gall stones necessarily were the cause of operation and death. If the operation killed and a stone was left behind how much more serious would a complete operation have been?

There were 108 cases. Among these gall stones were found in the gall bladder alone in 76. Gall stones caused the death of 9 of these, by setting up fatal trouble in the liver or gall bladder. The causes of death were, hepatitis cancer of the gall bladder, pancreatitis, abscess of liver. The remaining cases, 67, died of such conditions as pneumonia, nephritis, endocarditis, arteriosclerosis, cancer of stomach, fracture, tuberculosis, cancer of liver, etc.

There were 32 cases where the stones had passed beyond the gall bladder and were found in the ducts. In 14 of these the cause of death was due to the gall stones. The cause given being abscesses of liver, peritonitis, cholangitis, abscess of bladder, cholecystitis. The remaining 18 died of cardiac diseases, pneumonia, peritonitis, erysipelas, cancer of liver, etc.

From these figures it follows that if a patient with gall stones chooses medical treatment his chance of dying as a result of the gall stones is 14 out of 100 as long as they remain in the gall bladder. When the stones pass into the ducts his chances increase to 43 in 100. Should he elect operation while the stones are in the bladder what are his chances? His chances for death are then from 3 to 5 in 100.

The mortality of 3% for cholecystostomy and 4½% for cholecystectomy were given to me by Dr. E. A. Codman, who compiled a series of cases from various hospitals. The combined mortality of cholecystostomy and cholecystectomy in uncomplicated cases at the City Hospital is 5% plus.

The above figures are astonishingly large, but I offer them as they are. The relative mortality between gall stones in the bladder and those that have passed into the ducts is of special interest even though the figures themselves may for some unexplained reason be large.

The deduction is of course obvious, that advice for operation should follow the establishment of a diagnosis before the stones have time to set up any secondary fatal changes.

Incidentally it is of interest to note that in 4 out of the 108 cases a stone was found which had ulcerated through into the intestine.

Reports of Societies.

AMERICAN ASSOCIATION OF PHYSICIANS.

TWENTY-NINTH ANNUAL MEETING, HELD AT ATLANTIC CITY, NEW JERSEY, MAY 12, AND 13, 1914.

The President, DR. SIMON FLEXNER, in the Chair.

PRESIDENT'S ADDRESS.

PRESIDENT FLEXNER said the extension of the boundaries of knowledge has been such that it has compelled medical colleges to become departments of universities. This rapid extension of knowledge coincided with the active pursuit of physiology, pathology, bacteriology and pharmacology, either alone or in association with clinical studies for which special laboratories and institutes came to be established. Independent institutions for medical research had exercised a distinct influence on medical practice, but the foundation of these institutions was impossible until medical schools furnished an adequate supply of students whose training approximated that of the older European countries. All these conditions had acted more powerfully on clinical teaching. The professor of medicine in the university medical school had ceased long ago to be a general practitioner. The function of the clinical teacher had been newly defined within one or two decades. The American Association of Physicians had sympathized with every movement affecting the progress of medical education, and it favored this later step with the single hope, if it be in the real interest of medical progress, it might be given a chance to succeed.

CHRONIC INTERSTITIAL GASTRITIS.

DR. JOSEPH SAILER, of Philadelphia, reported a case of chronic interstitial gastritis in a male, 45 years of age, who had been subjected to various forms of medical treatment, but none of them was of any avail. Dr. Deaver performed an exploratory operation and found the condition of the stomach

entirely in accord with the clinical picture. The stomach walls were very thick. The stomach was adherent posteriorly and around the pylorus. The adhesions were released, and the stomach wall found greatly thickened. Dr. Deaver believed that gastroenterostomy would have been difficult, in addition to giving no definite relief. There were no enlarged glands along the lesser curvature, but the adhesions were dense along the greater curvature, and a definite gland mass could not be felt. There was no evidence of metastasis. The abdomen was closed and the patient made a satisfactory recovery from the exploratory operation.

DISCUSSION.

DR. DAVID RIESMAN, of Philadelphia, stated that with the x-ray we are not able to distinguish between the malignant and non-malignant types of what is called leather-bottle stomach. This distinction can be made only by clinical observation. Recently he saw a typical case of leather-bottle stomach which was very malignant, because the patient had cachexia and ascites. Both of these conditions in this case were sufficient to determine that the condition was cancerous. The man died in a few weeks. There were no evidences of metastases in the liver, and the liver was not enlarged at any time.

Another case that came to autopsy showed no metastasis from any of the viscera, but marked enlargement of the glands along the greater curvature of the stomach.

THE NATURE OF PERISTALSIS AND THE ACTION OF MAGNESIUM SULPHATE.

DR. S. J. MELTZER, of New York City, advanced two assumptions. One assumption made upon the basis of experimental facts was that peristalsis was a complicated condition in which the phenomenon of inhibition played an important part, and the second was, that magnesium sulphate acted by affecting this inhibitory force.

A CLINICAL STUDY OF ONE THOUSAND CASES OF CANCER OF THE STOMACH.

DR. JULIUS FRIEDENWALD, of Baltimore, presented a clinical study of 1000 cases of gastric cancer. The cases occurred in 10,416 patients, affected with various gastro-intestinal disturbances. The maximum liability to the disease occurred between the fortieth and sixtieth years. The greatest proportion occurred in males, 588 to 412 females. An hereditary history of cancer appeared in 9.4 per cent. of cases; a history of trauma in 1.9 per cent.; anemia was present in 82 per cent. Chronic endocarditis was present in 11.4 per cent.; arteriosclerosis in 69.6 per cent. A history of former indiscretions in diet was obtained in 32.1 per cent.; of alcoholism in 15.2 per cent.; of syphilis in 7.9 per cent.; hyperchlorhydria in 4.9 per cent.; hypochlorhydria in 2.8 per cent.; anacidity in 89.2 per cent. Lactic acid was present in 81.9 per cent. Dysphagia existed in 6.9 per cent. of all cases. Loss of weight existed in 88.5 per cent. Anorexia was present in 89.3 per cent. Vomiting existed in 89.3 per cent. Occult blood was present in the stools in 92.5 per cent. Masses in the form of tumors were detected in 71.9 per cent. Dilatation of the stomach existed in 46.7 per cent. Perforation occurred in 2.3 per cent. Metastasis existed in 67.2 per cent. Operations were performed in 26.6 per cent.

WHEN AND HOW TO USE TUBERCULIN PREPARATIONS IN PRIVATE PRACTICE.

DR. S. SOLIS-COHEN, of Philadelphia, in his paper with this title dealt with pulmonary tuberculosis only. The disastrous results of the early use of tuberculin were owing to (a) crude dosage; (b) unsuitability of cases.

1. *Dosage.*—Correct principles were established by Trudeau. The opsonic index of Wright marked a further advance. Latham's method of administration by mouth, with parallel temperature curve and opsonic index guidance, demonstrated the full trustworthiness of the temperature curve alone, and simplified the procedure.

The following was the author's modification of Latham's method: tuberculin residue (T. R.) triturated with milk, sugar was given with skim milk, whey or beef juice. The initial dose, he said, was one one-millionth of a milligram. Both subjective and objective symptoms of reaction were watched for. The dose was repeated once or twice weekly, according to result. It was gradually increased by increments of one one-millionth of a milligram to the reaction point, and then dropped one point lower, and so continued for some weeks. Later, a further increase was attempted, and if reaction was not shown, was proceeded with in a similar gradual way. The arbitrary increment of one one-millionth of a milligram was maintained during this remittent progression until one ten-thousandth of a milligram had been reached. After that, the increment might be raised to one one-hundred-thousandth of a milligram. Thus by successive stages a maximum dose was attained at a point determined for each individual by all the factors in the case, including the rapidity of the increase, character and intensity of reaction and maintenance of tolerance, as well as the local and general signs of improvement.

The treatment was continued with intermissions, for many months, and may be resumed, if necessary, from time to time over a period of years.

2. Selection of cases. In the majority of advanced cases, according to present knowledge, tuberculin was likely to be harmful. Experienced observers might employ it cautiously under conditions that seemed to call for its use, but others should avoid it, especially in cases showing a tendency to continuous fever, or in which there was, or had been recently, active softening. In the great bulk of early cases it was needless. Under proper treatment, medicinal as well as hygienic, recovery would take place without it.

Its field of action was in the treatment of cases which (1) had not passed beyond the stage of infiltration and which (2) had shown a certain degree of improvement under proper food, fresh air, judicious rest and exercise, and other approved measures, including the right drugs, but in which (3) improvement became sluggish or ceased, or retrogression took place. The slight additional stimulus afforded by an appropriate tuberculin preparation administered at well chosen times, and in correct dosage, would often reawaken the defensive and restorative processes of the organism and be followed by complete recovery.

Illustrative cases were cited.

DISCUSSION.

DR. ABRAHAM JACOBI, of New York City, had used tuberculin in doses of from one-hundred-thousandth of a milligram up to one-five-thousandth of a milligram, and had never seen any unpleasant symptoms. He had given it in combination with other agents. His routine treatment in chronic cases of pulmonary tuberculosis consisted in the internal administration of guaiacol and arsenic with tuberculin, and he had observed no disagreeable symptoms which he could attribute to the tuberculin.

SPLENECTOMY FOR PERNICIOUS ANEMIA.

DRS. WARREN COLEMAN AND JOHN A. HARTWELL, of New York, reported a typical case of pernicious anemia that grew steadily worse in spite of four months' treatment with arsenic, iron, hydrochloric acid, and four transfusions. Splenectomy was performed as a last resort. Ten weeks later, January 13, neosalvarsan was administered. The use of neosalvarsan made it impossible to draw any conclusion as to the effects of the splenectomy except in the interval before its administration. In this interval there was no evidence of more than temporary improvement. At the present time, April 24, six months after the operation, the patient, while looking better and feeling better, is just beginning to sit up.

STUDIES IN PERNICIOUS ANEMIA.

DR. HERBERT C. MOFFITT, of San Francisco, had been able to collect 31 cases of splenectomy for pernicious anemia from the literature, and he reported eight which were done in San Francisco, one in his own service.

The results from splenectomy had been variable. In eight cases death resulted either immediately or soon after operation. A number of other cases had not been improved. In still others reported in the literature surprising improvement had taken place. In his own case, paresthesia, which was obstinate before operation, disappeared at once afterward. There were other striking changes in the blood regeneration which followed soon after operation in many cases.

He had had opportunity to study the spleens after operation in eight cases, and the picture was practically the same in all. Contrary to clinical observations, the weight of the spleen was considerably greater than normal, varying from 450 to 500, and from that point down to 350 to approach the normal of 280. Most observers recorded the size of the spleen in pernicious anemia as not increased, while operative results showed the spleen was considerably larger than normal.

The recent work on splenectomy should not distract attention from the ultimate causes of the disease.

The author mentioned some time ago the similarity between pernicious anemia in man and pernicious anemia in animals, such as horses. Since that time he had had opportunity to observe some cases in animals and to make sections from the liver and spleen in certain cases. The microscopic appearance of the spleen and liver in these cases was that noticed in the organs removed at the operation for pernicious anemia. From a spleen removed in January an emulsion was made and injected hypodermically into a horse, with no change in the anemia. The operation of splenectomy in horses was difficult. Many arteries went into the spleen and possibly the operation could not be successfully done. He had in mind tying the arteries of horses whose spleens were affected with pernicious anemia, and it would be interesting to observe whether, as in human cases, cutting off the circulation in horses would have any effect in stopping hyper-hemolysis, which was characteristic of the disease in animals as it oftentimes was in human beings.

STUDIES IN EXPERIMENTAL ARTERIOSCLEROSIS.

DR. I. ADLER, of New York City, presented a preliminary report summarizing briefly the results of some experiments on dogs that he had carried on for some time. Dogs were injected, partly intravenously, partly subcutaneously, with various substances, such as adrenalin, nicotin, lead, diphtheria toxin, pure cultures of different species of bacteria, all with absolutely negative results.

In a further set of experiments dogs were fed with a number of substances, under varying conditions, and it was believed that some positive results were obtained, so that the aorta in some cases showed lesions which both microscopically as well as histologically were closely analogous, if not absolutely identical with human arteriosclerosis.

MITRAL STENOSIS.

DR. R. C. CABOT, of Boston, related his observations on 200 cases of mitral stenosis before and after death. His studies had impressed him with the fact that mitral stenosis fell into four clinical groups: 1. The cardiac group, in which the symptoms were apparently mechanical, such as stasis, etc. 2. The septic group, in which the symptoms were those of an acute infectious disease. 3. The embolic group, in which out of a clear sky embolism of the brain or periphery appeared. 4. That group in which there were no symptoms whatever, and the patient died of some other disease or after an operation and the pathologist found mitral stenosis after death.

CASE OF RECURRENT FEVER IN AORTIC ANEURYSM.

DR. ALEXANDER MCPHEDRAN, of Toronto, reported the case of a woman, aged 36, of irregular life and habits, who entered the hospital October 18, 1913, complaining of pain in the right chest for about six weeks. She had recurrent fever about every seven or eight days. The aortic arch was dilated and showed a pulsating aneurysm in the first left intercostal space. The temperature became normal and remained so in January, and her general condition improved very much. She was treated with iodids, mercury and salvarsan.

PATENT DUCTUS ARTERIOSUS WITH INFECTIVE PULMONARY ENDARTERITIS.

DR. W. F. HAMILTON AND DR. MAUDE E. ABBOTT, of Montreal, reported this case and drew the following conclusions:

1. This case illustrated in a remarkable manner what hitherto has not been fully emphasized, namely, that a vegetative process is commonly associated with congenital cardiac defects.

2. These vegetations in the present case, and probably in the majority of such processes occurring in conjunction with cardiac defects, were not a simple thrombosis of mechanical origin, with secondary infection supervening, but from their onset were inflammatory in character, the result of an invasion of the vessel wall by infective organisms at the seat of maximum strain.

3. The inflammatory process present in this case manifestly did not arise as a result of an embolic infection through the vasa vasorum, but began by the invasions of the intima at a single point, the pulmonary end of the ductus, which was probably the seat of maximum strain from the two combined causes, the eddying blood stream within its lumen, and the rigid calcareous gland which lay in close juxtaposition without.

4. The present, so far as they knew, was the only recorded case in which the ductus and pulmonary artery in the neighborhood were the sole seat of the disease and in which the pulmonary orifice of the ductus had been demonstrated to be the initial seat of the lesion.

DISCUSSION.

DR. W. S. THAYER, of Baltimore, had had a case very closely similar to the one related in which there was an increased area of dullness in the second and third interspaces, a thrill, and a prolonged murmur beginning in systole and lasting over diastole with an accentuated second pulmonic sound. The diagnosis was open ductus arteriosus. As time went on the patient developed paralysis of the left recurrent laryngeal nerve. The patient was sent to a well known radiologist who took an x-ray and in sending the plates back wrote a letter in which he made an exact diagnosis of the condition from his standpoint, stating, "this is an instance of mitral stenosis with dilatation of the left auricle, and pressure upon the recurrent laryngeal nerve," but it did not occur to the radiologist that there were other methods of making the diagnosis.

DR. ABRAHAM JACOBI, of New York City, said that he knew a baby when he was only a few months old. He was now a boy twelve years of age. His ductus had been closed nearly three years. He saw him once or twice every year and always found the same symptoms, the murmur getting less and less marked until finally it disappeared not only from the carotids but also from the pulmonary artery from below up.

CERTAIN TESTS OF RENAL FUNCTION.

DR. W. S. THAYER, of Baltimore, related 18 instances of severe advanced chronic nephritis, and concluded that where he had been able to correlate the anatomical and clinical observations, they served to fortify and to verify his previous opinion that the phthalein test was a reliable one of considerable diagnostic and prognostic value, especially in the study of chronic nephritis.

DISCUSSION.

DR. CHARLES F. WITHINGTON, of Boston, reported several cases of nephritis. One of the patients, a man, brought into the hospital unconscious, showed unmistakable symptoms or evidence of acute nephritis. There was a history of convulsions and of his being comatose. Twenty-four hours after he was brought in the phthalein output was 70 per cent. His condition proceeded to clear up and he went out about two weeks after he was brought in, showing a surprising phthalein output, although manifesting signs of nephritis.

DR. JOSEPH L. MILLER, of Chicago, stated that a man came to the hospital, not very ill, in whose case a definite diagnosis of chronic interstitial nephritis was made. He was passing 2000 c.c. of urine a day. He could not get a trace of phthalein through in two hours. In forty-eight hours and up to the time he went into coma, he passed a large amount of urine, and at the end of that time went into coma and died. Autopsy showed a high degree of interstitial nephritis.

DR. THAYER (closing): said there were many instances of hydropic nephritis with very few grave subjective symptoms excepting the hydrops. One found sometimes large quantities of albumin and casts in the urine, yet there was perfectly normal renal function if we estimated it by these tests, excepting the question of salt retention.

SYPHILITIC NEPHRITIS

DR. ALFRED STENGEL AND DR. J. HAROLD AUSTIN, of Philadelphia, in a joint paper stated they had examined the urine with the polarizing microscope fifty-eight times from forty-six cases. Of these 46, 23 showed nephritis with an abundance of albumin and casts in the urine. Of these 23 cases, six had positive Wassermanns, 3 had strong presumptive evidence of syphilis, but no positive Wassermanns; 14 had not the slightest evidence of syphilis. The six cases with positive Wassermanns, all showed lipoids in the urine. The rest of the 46 cases studied were made up in part of nephritis cases of the interstitial or arteriosclerotic types, with only traces of albumin in the urine, and a few hyaline and granular casts, some with syphilis and some without, any number of cases of syphilis but with no nephritis, and any number of control cases with neither syphilis nor nephritis. None of these cases showed lipoids in the urine. One of the six syphilitic cases with nephritis showing lipoids in the urine had not received any mercury.

They found of further interest the fact that of their last 84 cases of nephritis, for 46 cases there could be recognized from the histories such accepted etiological influences as infections, lead, alcohol, excessive work, exposure, senility, etc., but that for 18 cases no such factors could be determined. Of these 18 cases, there existed in eight either an unquestionable history of syphilis or a positive Wassermann or both, and in six more of these cases no Wassermann had been secured.

In order to determine whether the common experimental degenerative nephritides of animals would be associated with lipoids in the urine, three rabbits were given uranium nephritis and one dog a chromate nephritis. The four experiments were negative; no lipoids were found in the urine. Further experiments with mercurial nephritis, phosphorus and chloroform lesions and syphlitic inoculations were in progress.

X-RAY EVIDENCE IN EARLY AND LATENT CANCER OF THE STOMACH.

DRS. FRANKLIN W. WHITE AND RALPH D. LEONARD, of Boston, said their material consisted of 114 hospital and private cases suspected of having can-

cer of the stomach, thoroughly examined within a year by clinical and x-ray methods. In forty cases cancer was proved; in sixty-six it was ruled out; in eight the diagnosis remained doubtful. The group of cases was studied to determine how far the x-ray evidence had helped to detect early or latent cancer. Recent cases were chosen because of recent improvements in x-ray technic. The x-ray evidence in early cancer was very scanty; in latent cancer it was abundant and important. In the group of operated cases of cancer, a comparison of correct diagnosis before and after x-ray examination showed the latter distinctly higher.

THE PATHOLOGIC EVIDENCE OF THE RELATIONSHIP BETWEEN GASTRIC ULCER AND GASTRIC CARCINOMA.

DR. LOUIS B. WILSON, of Rochester, Minnesota, stated that any existing disagreement as to the relationship between gastric ulcer and gastric carcinoma depended on (1) failure to understand the pathologic data. (2) Inappreciation of the bearing on the clinical data; or (3) failure to appreciate the correlation existing between the two.

Small gastric ulcers were usually simple and large cauliflower cancers usually showed little evidence of previous ulceration, but between these two lay a large group of ulcerated lesions of the stomach, some of which were ulcers only and others of which resembled ulcers in all respects, except that in addition they also showed cancer.

So far as the pathologist was concerned, he could not positively distinguish, in many such specimens, between simple ulcer and ulcer plus cancer, except with a microscope. When, in such a specimen showing cancerous areas, no cancer cells were found in the base of the ulcer one was warranted in assuming that the ulcerative lesion preceded the cancer.

A review now in progress of all the tissue removed from the stomach and duodenum in the Mayo clinic since 1905 showed that approximately 60 per cent. of the specimens which showed cancer gave more or less pathologic evidence of the precedence of ulcer in the same area.

Of the specimens of gastric tumors examined pathologically and diagnosed either cancer or cancer on ulcer, there was agreement between the clinical diagnosis and the pathologic diagnosis in more than 80 per cent. of the cases.

THE INSPIRATORY EXAGGERATION OF THE DICROTIC WAVE IN PERICARDITIS.

DR. ALBERT E. TAUSSIG, of St. Louis, Mo., stated that ordinarily, the dicrotic wave in the radial sphygmogram did not vary in size with the phase of respiration. In pericarditis, however, it became more or less exaggerated, sometimes greatly so, during inspiration. In all of the five cases studied from this point of view, the phenomenon was observed. Anatomical considerations rendered its occurrence readily explicable. It might have diagnostic significance.

INTRAUTERINE AMPUTATION.

DR. GEO. DOCK, of St. Louis, Mo., reported a case bearing on the pathology of so-called congenital amputation with x-rays and photographs.

THE ETIOLOGY OF SOME OF THE INFECTIVE TROPICAL GRANULOMATA.

DR. RICHARD P. STRONG, of Boston, stated that among the infective granulomata which occurred more commonly in certain tropical countries, which were perhaps of unusual interest from an etiologic point of view, were verruga peruviana ulcerating granuloma of the pudenda, and framboesia. The relation of these forms to one another was considered.

Verruga peruviana and oroya fever had been considered to be merely different stages of the same disease, oroya fever having been regarded as the initial stage of the granulomatous verruga stage. The two diseases, however, were quite distinct and had a very different etiology. Verruga peruviana was due to a virus which might be transmitted to some of the lower animals, while oroya fever owed its origin to a parasite of the red blood corpuscles. The two diseases also had a very different pathology.

The etiology of ulcerating granuloma did not seem to be definitely determined.

In view of the recent work in the transmission of the virus of verruga to some of the lower animals, it was recommended that more extensive experiments be carried out with the idea of transmitting ulcerating granuloma to monkeys.

A DIFFERENTIAL STUDY OF COCCIDIOIDAL DISEASE AND BLASTOMYCOSIS.

DRS. P. K. BROWN AND W. T. CUMMINS, of San Francisco, stated that cats and white rats were found to be markedly insusceptible to infection. Rabbits and guinea-pigs appeared to be somewhat more susceptible to coccidioidal than blastomycetic infection. Coccidioidal involvement was noted in two rabbits, while the cerebrospinal tissues remained unaffected in all animals in advanced disease. Passage through animals exalted the virulence of the organisms. Highly acid and alkaline agar offered but little inhibition to the growth of the organisms. There was profuse aerobic growth in, but no fermentation of, eighteen sugars. Fifty dyes were studied for their inhibiting effect upon the growth of the organisms. Crystal violet was found to be the most inhibitive and in concentration forty times greater than the minimum inhibitory dose, was not toxic for guinea-pigs and white rats.

They discussed the differentiation of the two diseases clinically, pathologically, and bacteriologically and by animal experimentation.

THE INFLUENCE OF BENZOL INHALATIONS ON EXPERIMENTAL PULMONARY TUBERCULOSIS IN RABBITS.

DR. WILLIAM CHARLES WHITE, of Pittsburgh, stated that benzol C_6H_6 was the best solvent for the fat portion of the tubercle bacillus. It extracted a greater percentage of fat than any other single solvent would take from the bacilliary substance. Because benzol could be easily vaporized and utilized as an anesthetic, it was thought possible in this way to dissolve living tubercle bacilli after their entrance into the pulmonary capillary system by way of the ear vein and before the formation of the tubercle.

It was hoped in this way to obtain a solution of all the living portions of the tubercle bacillus within the body and the possible development of a retarda-

tion of the process produced by a fatal dose of tubercle bacilli and the establishment of an immunity to a further dose of the organism. Contrary to the desire expressed in the theory, he found that in every instance whether the infecting tubercle bacilli were of low virulence or of high virulence, the resulting infection in rabbits was very much more severe in those treated by inhalation of benzol than in those infected with the same weight of infecting organism.

The symptoms produced in rabbits by the inhalation of benzol were similar to those described by Torald Sollmann for the inhalation of gasoline vapors. Animals might be given benzol inhalations, 5 c.c. every second day for periods up to three and even four weeks without resulting in death. The resulting leucopenia varied very much, the lowest white cell count was 3800 per cm. The red cell anemia was very variable, the lowest in our series being 3,600,000 per cm. The majority retained a normal red cell count.

The blood smears and counts exhibited changes similar to those described for the injections of benzol by Selling and others.

In all thirty-three animals were used; twelve controls and twenty-one treated. The pathologic findings in many of these animals were very striking. In thirty per cent. of the treated animals, after receiving 5 c.c. inhalations of benzol every second day for three weeks, and then being allowed to live two to three weeks longer, extreme enlargement of the spleen was found. In one instance the spleen measured 13 x 3.5 x 3 cms., and the circumference of its largest part was 9.5 cms. There was a large hemorrhage in the substance of this spleen.

There was in all twenty-one treated animals but a single case of purpura with hemorrhages into the mucous membrane of the stomach and bowel.

There were marked fatty changes both in the liver and the kidneys of the treated animals.

SOME RELATIONS OF THE BRAIN AND OF THE OLFACTORY APPARATUS TO THE PROCESSES OF IMMUNITY.

DR. HENRY SEWELL, Denver, Colorado, drew the following conclusions from his experimental work on this subject:

1. Guinea-pigs sensitized to horse serum may be desensitized by residence in a horse stable.
2. It was probable that this reaction might be rapidly achieved through the olfactory sense or more slowly by absorption through the respiratory membrane.
3. The period of anti-anaphylaxis was of less than two days' duration.
4. The converse of this, sensitization of normal guinea-pigs in stable air he had not been able to achieve.
5. Removal of part of the brain of a sensitized guinea-pig produced much more severe shock than the same amount of injury in a normal animal.
6. This shock was apt to be followed by a period of anti-anaphylaxis of short duration.
7. Section of the olfactory nerves within the cranial cavity preceding the brain operation by a day or more abolished the tendency to shock.
8. Such nerve section in the normal animal also seemed to reduce the shock arising from definite brain injury.

Depression of the olfactory sense through cocain and the resemblance of symptoms from poisoning with this drug to those of anaphylaxis were discussed.

The body as a whole might be sensitized through the peripheral application of horse serum after a definite latent period which did not seem to be affected by previous general sensitization.

THE NORMAL AMOUNT OF DIASTATIC FERMENT IN THE URINE AND FECES AND ITS VARIATION IN DISEASES OF THE PANCREAS.

DR. THOMAS R. BROWN, of Baltimore, stated that from his study of the diastase-content of urine and feces in normal and in certain pathologic conditions, the following conclusions could be drawn:

1. In healthy individuals the diastase-content of the urine falls within quite definite limits. Markedly small amounts of this ferment in the urine, in the absence of renal changes, were suggestive, although not diagnostic, of pancreatic disease, but the real value of these normal limits would probably be in furnishing criteria in testing the renal function by the diastase output of the urine.
2. The stool, if rigorously exact methods are carried out as to food (milk), purgative employed, preservation of specimen, estimation of ferment, etc., also furnished a content within definite limits. He could not insist too strongly upon the procedure being exactly the same in all cases. The effect of waiting too long after the stool has been obtained before making the examination, the influence of variations in temperature in the place where it was kept, and of different laxatives and different foods, was so great as to render the results obtained by methods in which insistence upon such a rigorous technic had not been made of much less value.
3. Extensive carcinoma of the pancreas showed no diastase in the tubes of least dilution in his method, and this absence of ferment should prove of help in the diagnosis of this condition.
4. In chronic pancreatitis diastase was present in the stool, but in markedly diminished amounts.
5. In achylia gastrica the diastase-content of the stool was practically normal in all the cases examined. This, in the first place, suggested that in the absence of hydrochloric acid some other method of pancreas invasion was called into play; and, in the second place, that the diarrhea met with in certain of these cases of achylia gastrica—the so-called gastrogenous diarrheas—was not of pancreatic origin.
6. If all the controllable factors were standardized, the results obtained by the study of the diastase-content of the stool should be of real value in the diagnosis of pancreatic disease and in the study of functional disturbances of this gland.

ACONITE AS A VASO-DILATOR.

DR. WILLIAM HANNA THOMSON, of New York City, stated that after many years of experience in the use of aconite in chronic interstitial nephritis, he regarded it as the most efficacious vasodilator which we possessed, when given systematically in full doses. Aconite thus administered reduced, at once, the blood pressure, produced a full and compressible pulse, and greatly increased the percentage of the elimination of urea in interstitial nephritis. The most important action of aconite, when administered in interstitial nephritis, was to increase the elimination of urea. The beneficial effects of aconite were particularly pronounced in mental derange-

ments of the nature of melancholia with high blood pressure.

THE SUBCUTANEOUS ADMINISTRATION OF OXYGEN AS A THERAPEUTIC MEASURE.

DR. JOHN MCCRAE, of Philadelphia, stated that he had used oxygen in this way for the last two or three months and believed it was the rational method of administering it, and properly placed, it was useful. He had had occasion to employ it in a surgical case which had a severe operation. The patient looked as though he might die in a short time. His respiration was 60; he had extreme edema of the lungs, extreme pallor, profuse perspiration, and signs of impending death. With repeated injections of oxygen the man recovered. He had used oxygen in thirty cases and believed it should be a part of the armamentarium of the surgical operating room.

INFECTIOUS AND TOXIC FORMS OF TRANSVERSE MYELITIS.

DR. B. SACHS, of New York City, reported five cases of complete transverse myelitis. Of this number, four recovered completely, and one proved fatal.

The first of these cases he reported two years ago with the idea that the transverse myelitis was due to the poliomyelitis virus, that statement being based on the fact that the case appeared during the epidemic of poliomyelitis in New York City, and in many respects it was similar to poliomyelitis. There was some peculiar form of infectious transverse myelitis which in four out of five cases led to recovery. The condition was more common than heretofore supposed and should receive further consideration.

EPIDEMIC OF STREPTOCOCCUS SORE THROAT.

DR. JOSEPH A. CAPPS AND DR. J. D. DAVIS, of Chicago, described in a joint communication an epidemic of streptococcus sore throat in Jacksonville, Illinois, which was traced to the milk of cows affected with streptococcic mastitis.

DISCUSSION.

DR. GEO. M. KOBER, of Washington, D. C., pointed out that he made his first collection of milk-borne epidemics in 1894, and at that time was impressed with the studies made in England by Kline, Crookshank, and others in regard to so-called epidemics of scarlet fever which they attributed at that time to an inflammatory condition of the teat or udder of the animal. In analyzing the situation he concluded and ventured to express the opinion in 1895 that these were not true cases of scarlet fever, but typical instances of either staphylococcic or streptococcic infections, because he had seen a great many instances where an eruption similar to that observed in cases of scarlet fever was due to streptococcus infection.

With our present knowledge of milk-borne diseases, nothing short of pasteurization of milk would confer immunity from these infections.

DR. R. C. CABOT, of Boston, asked what sort of an eruption it was.

DR. CAPPS replied that it was erythematous. Four of the cases were described and diagnosed by very good clinicians as erysipelas.

PATHOGENESIS OF POLIOMYELITIS IN THE LIGHT OF RECENT RESEARCH.

DR. SIMON FLEXNER, of New York City, stated that recent experimental studies on poliomyelitis confirmed the view that in man infection occurred through the upper respiratory tract, and that the virus passed to the central nervous organs by way of the cerebrospinal fluid and not by way of the blood.

Book Reviews.

Die Moderne Therapie der Gonorrhöe beim Manne. Ein Leitfaden für Studierende und Aerzte. Von PROF. DR. PAUL ASCH, in Strassburg i. Els. Mit 25 Abbildungen in Text. Bonn: A. Marcus and E. Webers Verlag. 1914.

This small pamphlet of eighty-one pages contains twelve short lectures which embody the author's fifteen years' experience in the treatment of this disease. There is no attempt at completeness, and the writer states in his preface that his sole object is to present in brief form, his own beliefs and opinions as acquired from his own experience. The German is terse and vigorous and no words are wasted, so there is much knowledge contained in a small space. Type and paper are excellent, and there are twenty-five sketches, chiefly of instruments in common use.

Modern Medicine, Its Theory and Practice. In Original Contributions by American and Foreign Authors. Edited by SIR WILLIAM OSLER, Bart., M.D., F.R.S.; and THOMAS MCCRAE, M.D. Volume II, Diseases Caused by Protozoa and Animal Parasites, Diseases Due to Physical, Chemical and Organic Agents, Diseases of Metabolism and of the Respiratory System. Second edition, thoroughly revised. Illustrated. Philadelphia and New York: Lea and Febiger. 1914.

The second volume of this standard text-book requires little in the way of comment. The eminent authors have revised their special sections; there is a new section on pellagra. Dr. Osler and Dr. Churchman have written an authoritative article on syphilis.

A Manual of Clinical Diagnosis by Means of Laboratory Methods. By CHARLES E. SIMON, M.D. Eighth edition, enlarged and thoroughly revised. Philadelphia and New York: Lea and Febiger. 1914.

The eighth edition of this well-known manual has grown to eight hundred pages. Like its predecessors, it contains all the modern methods of laboratory diagnosis. There is an adequate discussion on complement fixation tests, renal function tests, and the Abderhalden's pregnancy test.

Forensic Medicine and Toxicology. By G. O. HAWTHORNE, M.D., fellow of the Royal Faculty of Physicians and Surgeons of Glasgow, lecturer on Forensic Medicine in the London School of Medicine for Women; physician to the North-West London and Royal Waterloo Hospitals. Third edition. New York: Longmans, Green and Company. London: Edward Arnold. 1914.

In this book the author has given a remarkably clear and definite statement of the distinction between the expert, drawing inferences from facts, and the ordinary witness testifying to facts. It can be readily seen that usages in English courts are somewhat different from our own. In the detection of blood stains the author states that there are no means by which menstrual blood can be differentiated from blood from a wound, yet this formed an important point in the Tucker trial, where the presence of menstrual blood was determined by the association of vaginal cells. The author is up to date in his illustrations and references, using the Crippen case for proof of the positive application of the Vitali test to vegetable alkaloids (hyoscin, hyoscyamin and atropin) alone, and not to the mydriatic animal alkaloid (ptomaines). Full attention is paid to the danger of water gas with its dangerous carbon monoxide. Another fact upon which he dwells, illustrated by a fatal case of poisoning, is that illuminating gas may make its way into a house from a broken street main, cause the death of an individual in the room, without an explosion, though a burning light was constantly present. His differential diagnosis of the causes of unconsciousness could be read with profit by every police surgeon, where the presence of cerebral disease or alcoholism has often to be decided and by whom a mistake is frequently made. Although, as stated, the practices of the courts of Britain differ from those of our own, so much marked good sense is contained in this book that it can be perused with profit by all interested in medical jurisprudence.

Practical Sanitation. By GARDNER AND SIMONDS. St. Louis: C. V. Mosby Company. 1914.

The authors of this book have accomplished their object of providing a plain, non-technical exposition of the duties of the health officer. With this volume at hand the health officer should certainly be able to cope more efficiently with the exigencies of his duties. It is obviously not intended for the man in charge of large city or state health organizations, but should admirably meet the needs of the health official of small municipal or rural communities, and should be readily comprehensible to the non-medical man.

Part I, which takes up the consideration of epidemiology, gives information in regard to the management of epidemics, isolation and quarantine, isolation hospitals and camps, and disinfection, which could not readily be found except by a man with a large library at hand. The grouping of the diseases is perhaps not entirely logical, and the discussion of the diseases might well be more from a sanitary and hygienic point of view rather than clinical.

Part II, on general sanitation, should prove extremely valuable as indicating the lines along which the duties and opportunities of the health officer lead, and in guiding him in the methods of carrying out his work. The all-important subject of vital statistics is given due prominence, and is presented in such a manner as to enable the local health officer to keep satisfactory records of his community, even though he had no previous statistical training. In this section of the book are also taken up such matters as the inspection of schools, factories, and public institutions, the disposal of sewage and garbage, the subject of soil pollution, the conduct of various campaigns, as those against rats and flies, and finally the inspection of food, including milk and water.

Of course the legal aspect of health work could not be given a comprehensive discussion in a book of this nature, as the problem is one which varies with each community; but a number of valuable hints are given which should be of great value to the sanitarian in his relation with the law.

Part III, which deals with laboratory methods, would be of more value if, instead of limiting itself too much to methods of collecting samples and transporting them to the laboratory, would take up at least the simpler laboratory technic in a manner which would enable the reader to undertake these processes.

The book on the whole, while not being a textbook on sanitation, undoubtedly fills a long-felt want, and should go far toward improving the health administration of the smaller localities. The principles laid down are certainly in accord with the accepted teachings, and while being thoroughly up to date, do not advocate any of the extremely recent and untried methods.

THE BOSTON

Medical and Surgical Journal

THURSDAY, JUNE 18, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

ANNOUNCEMENT.

ON April 10, 1914, the BOSTON MEDICAL AND SURGICAL JOURNAL passed into the hands of new owners. On June 10, 1914, the Council of the Massachusetts Medical Society adopted the recommendations of its Committee of Nine, looking toward an affiliation between the Massachusetts Medical Society and the BOSTON MEDICAL AND SURGICAL JOURNAL.

We, the new owners, desire to express our appreciation of the confidence thus shown in the new management, and assure the members of the Massachusetts Medical Society that we will make it one of the chief concerns of the JOURNAL efficiently to serve the Society, whose official organ it will thus become. We feel that with this association the first step has been taken toward enlarging the scope of the JOURNAL.

We recognize the dignified position which this, the oldest weekly medical journal in America, has always held. Our purpose is to maintain this position of dignity. Our hope is that in the future the JOURNAL may become the most important medium of expression for scientific and clinical medicine in the East, and with courage and timeliness may serve the needs of the community.

Our predecessors in ownership accepted the JOURNAL as a trust, deriving no personal profit therefrom. We, in the same spirit, agree to devote to the realization of those hopes we have expressed, any revenue above expenses which the JOURNAL may afford.

We shall welcome criticism of every sort and from all sources, and we ask the help of all those who have the best interests of medicine at heart.

JOEL E. GOLDTHWAIT, M.D.,
EDWARD C. STREETER, M.D.,
HUGH WILLIAMS, M.D.

MASSACHUSETTS MEDICAL SOCIETY.

THE one hundred and thirty-third annual meeting of The Massachusetts Medical Society was held in Boston on Tuesday and Wednesday of last week, June 9 and 10. The weather of the first day was unseasonably cold, that of the second day very hot; but all the exercises and sessions were well attended.

During the forenoon of June 9 members of the Society were invited to attend specially arranged medical and surgical clinics and demonstrations at the principal Boston hospitals. The annual meeting of the Council was held at noon on this day, and in the afternoon the sections of medicine, surgery, and tuberculosis held their separate sessions at the Copley-Plaza Hotel.

The Shattuck Lecture was delivered in the evening of June 9 by Dr. Herbert C. Moffitt of San Francisco, Cal., and was well received by a large audience of members. It will be published in full in a later issue of the JOURNAL. Following the lecture there was an informal reception by the President and a most enjoyable pop concert, with light refreshments, in the ball room.

On the morning of Wednesday, June 10, the annual meeting of the Society was held at the Copley-Plaza. Dr. Charles F. Withington, of Boston, was elected president for the ensuing year. Dr. Samuel B. Woodward, of Worcester, was elected vice-president; and Dr. Everett A. Bates, of Springfield, orator to deliver the annual discourse in 1915. At noon the annual discourse of this year was delivered by Dr. Horace D. Arnold, dean of the Harvard Graduate School of Medicine.

Dr. Arnold touched upon many current medical and sociologic problems, on medical education, the registration of physicians, health education of the public, the milk problem, and med-

ical legislation. Of the recent anti-vaccination movement, he spoke as follows:—

"Our recent experience with the vaccination laws shows the danger of public indifference. The present generation knows practically nothing about this loathsome disease of smallpox, which was formerly a veritable scourge, and a great many physicians have never seen a case. People have come to accept this freedom from smallpox as a matter of course, and they are apt to forget that constant vigilance on the part of the health authorities and the continued protection of vaccination alone stand between them and the possibility of a serious outbreak of this disease. It is greatly to the credit of the representatives that they were not carried off their feet by the fierce onslaught of the friends of the bill.

"The danger is passed for the time being, but it is not eliminated. But in this connection the medical profession has a duty to itself. It should see that its members are above criticism in the way vaccination is performed. Let us be frank about the matter. There is danger in vaccination—not in the vaccine itself, but in careless methods of using it. In Massachusetts a clean safe virus is furnished by the state to all citizens free of charge. It is a fact that a certain small number of cases of infection do result either because the physician is careless in the operation or because he does not sufficiently instruct the patient about the after-care. It should be considered as much a disgrace to a physician to have an infected wound follow vaccination as it is to have it follow a surgical operation, for it is equally avoidable.

"This is an active issue between the profession and the public. A certain number of persons have just reason to complain of the results of vaccination when it has been improperly performed. In their ignorance they attach the blame to the procedure itself, instead of to carelessness. And the reputation of the whole profession suffers because we thus tacitly shoulder the errors of incompetent practitioners."

In the afternoon of June 10 the combined meeting of the three sections of the Society was held at the Massachusetts General Hospital. The annual dinner at the Copley-Plaza in the evening was attended by 850 members and guests. The retiring president, Dr. W. P. Bowers, of Clinton, Mass., was toastmaster, and addresses were made by Governor Walsh, Bishop Lawrence, Dr. Frederick C. Shattuck of Boston, Dr. Edward L. Martin of Philadelphia, Dr. Herbert C. Moffitt of San Francisco, Dr. James W. Kerr of Washington, assistant surgeon-general of the United States Public Health Service, and Dr. Withington, the president-elect of the Society.

The meeting was in every feature a success, and especial credit is due the members of the committee of arrangements, whose efficiency and hard work made this success a possibility and a reality.

MEDICAL LEGISLATION. MASSACHUSETTS STATE BOARD OF INSANITY.

WHILE the subject of the organization of the Massachusetts State Board of Insanity, to which we made editorial reference in the issue of the JOURNAL for April 9 (p. 584), is under consideration by the joint legislative committees on ways and means and public institutions, a tentative bill has been prepared for discussion by those committees. This bill provides for a board of insanity, to consist of three members, to be appointed by the governor for terms of three years, one to retire every year, and each to be paid a salary.

"The chairman is to be designated by the governor and all are to devote their whole time to the work. At least one member must be an expert in matters relating to insanity and the insane. The bill removes prohibition against the appointment of members of the present General Court. Any member may for cause be removed by the governor. The bill also provides for a paid executive secretary, who must be a physician and an expert on insanity.

"In addition to its present powers, the board is given charge of all insane, feeble-minded, and epileptic persons, and persons addicted to the intemperate use of narcotics or stimulants, the care of whom is vested in the Commonwealth by law, and of all institutions or buildings owned by the Commonwealth and used for the care of such persons. The Norfolk State Hospital and the hospital cottages for children are excepted. These are to be in charge of the State Board of Charity.

"For each institution under control of the board there is to be a board of seven trustees, five men and two women. There must be thorough visitations of each institution by two of the trustees at least once in two weeks, and by a majority of them quarterly, and by the whole board semi-annually; and after each of such visits a written account of the condition of the institution must be transmitted to the State Board of Insanity. The trustees are to receive no compensation for their services."

In general, the provisions of this plan seem well conceived and adequate. Its further discussion in committee will doubtless lead to suggestions for its satisfactory improvement.

THE SURGEON-GENERAL'S LIBRARY.

IN the United States Army appropriation bill, which passed the Senate some weeks ago, it was provided that the appropriation for the Surgeon-General's Library shall be conditional upon its merging with the Congressional Library, of which it shall became a subordinate department. This provision was inserted without consultation with either the surgeon-general or the librarian of congress, and seems a most unwarrantable piece of aggression. As a matter of fact both of them are opposed to the change. Whatever might be the administrative conveniences of such a step, they would be more than outweighed by the disadvantages of curtailing the independence and abrogating the autonomy of the largest and most valuable medical library in America. It is sincerely to be hoped that this objectionable provision will be stricken from the appropriation bill in its consideration before the House.

MEDICAL NOTES.

LONDON DEATH-RATES IN APRIL.—Statistics recently published show that the total death-rate of London for April, 1914, was only 13.8 per 1000 inhabitants. Among the several districts and boroughs the highest rate was 19.1 in Finsbury, a crowded central slum, and the lowest was 9.9 in Lewisham, a suburb on the south.

AN OUTRAGE IN DUNDEE.—The following political outrage at Dundee is reported in a recent issue of the *Lancet*:—

"A new hospital for women in Dundee, which was on the point of completion, was partly destroyed by fire in the early morning of May 22nd. The hospital was to have been opened next week. The damage is estimated at some £2000 or possibly more. The hospital, a two-storied building, was erected through the liberality of a number of leading citizens, and was designed to take the place of the present hospital for women in Seafieldroad, which falls to be vacated next week. The new hospital was begun nearly two years go, and every effort was being made to get it ready for occupation. It is generally assumed that the fire was the work of suffragists. Messages such as are common in other incidents of the kind were found. It is believed that six months will be required to get the damage repaired, and although the numbers at the old hospital were being kept down with a view to the removing from one premises to the other, it is probable that temporary accommodation will have to be provided. Fortunately the loss is covered by insurance."

EXPERIENCE WITH VACCINATION AT BELFAST.—In connection with our recent local discussions about vaccination, the following item from Belfast, Ireland, seems of interest:—

"A convincing statement has been sent to the Belfast board of guardians from the council of the Ulster Medical Society and from the executive committee of the British Medical Association (Belfast division) in reference to the campaign now being conducted in Belfast against vaccination. Details of local experience and of great importance are given. In the last outbreak of smallpox in Belfast (1904-05) out of 178 cases there were 9 deaths. Of those attacked, 146 had been vaccinated and 2 of them died, while of 32 who had never been vaccinated 7 died. Thus, 1 out of every 5 unvaccinated people who contracted smallpox died, while of every 73 vaccinated only one succumbed. There was not a single case of smallpox in a revaccinated person. Moreover, the medical superintendent of the Belfast Fever Hospital, whose experience extends over 20 years and covers six outbreaks, has never had a case of smallpox in a revaccinated person."

HONOR FOR DR. LOEB.—It is announced that Dr. Jacques Loeb, of the Rockefeller Institute for Medical Research, has been elected a corresponding member of the section of anatomy and zoölogy of the Paris Academy of Sciences, in succession to the late Lord Avebury.

HONORARY DEGREE FOR DR. AGRAMONTE.—At the recent commencement exercises of Columbia University, one of the seven honorary degrees of D.Sc., was conferred on Dr. Aristides Agramonte, of Havana. In awarding the degree President Butler addressed Dr. Agramonte as follows:—

"Aristides Agramonte—Bachelor of Arts of the University of Havana, and Doctor of Medicine of Columbia University of the class of 1892; sole survivor of a famous group of scientists and public servants who, in order to test the theory of the transmission of yellow fever by mosquitoes, began the experiments on themselves; and who have lived to see your native island freed, largely through your own efforts, of its worst scourge; professor of bacteriology and experimental pathology in the University of Havana."

No one can fail to recall in this connection President Eliot's characterization of Dr. Walter

Reed, in conferring upon him the honorary degree of A.M. at Harvard in 1902, as "the army surgeon who planned and directed in Cuba the experiments which have given man control over that fearful scourge, yellow fever."

PLANS FOR A NATIONAL LEPROSARIUM.—Report from Washington, D.C., states that on June 4 two bills pertaining to leprosy were introduced into the national House of Representatives. One of these authorizes the surgeon-general of the United States Public Health Service to select an island in any insular or territorial possession for use as a national home for lepers, appropriating $150,000 for that purpose. The other bill appropriates $500,000 for the same purpose, the site for the leprosarium to be selected by the surgeons-general of the Army, Navy, and Public Health Service.

A CENTENARIAN.—Mrs. Anthony Lossaso, who died on June 7 at Paterson, N.J., is said to have been born in 1804 in Italy. She married her fifth husband in 1909.

THE ITALIAN QUINTUPLETS.—In the issue of the JOURNAL for May 28, we published a communication relative to the reported birth of quintuplets at Palermo in Italy. In the issue of *La Domenica del Corriere*, a Milan paper, for May 31, is a statement confirming this report, with a colored frontispiece showing the parents, the doctor, and five nurses holding the five babies.

BOSTON AND NEW ENGLAND.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending June 9, 1914: Diphtheria, 45, of which 2 were non-residents; scarlatina, 68, of which 9 were non-residents; typhoid fever, 3; measles, 168, of which 1 was non-resident; tuberculosis, 77, of which 1 was non-resident.

The death-rate of the reported deaths for the week was 16.04.

FIFTIETH ANNIVERSARY OF BOSTON CITY HOSPITAL.—Invitations are issued by the Trustees of the Boston City Hospital to the semi-centennial observance of the opening of the hospital, which will be celebrated with appropriate exercises in the surgical amphitheatre on Saturday of this week, June 20, at 11.30 a.m. The twenty-fifth annual meeting of the Boston City Hospital Alumni Association will be held at the Copley-Plaza Hotel on the same day, at 6.30 p.m. Dinner will be served at 7 o'clock, immediately after the business meeting. Dr. Philip Coombs Knapp will preside. The following are the invited guests, some of whom will speak: The Trustees of the Hospital, His Excellency the Governor of Massachusetts, His Honor the Mayor of Boston, Hon. Samuel W. McCall, Major-General Hugh Bancroft, Herbert G. Woodworth, Esq., Dr. Josiah N. Hall, Dr. H. C. Baldwin, Dr. John G. Blake, and the President-elect of the Alumni Association.

LIVING CENTENARIANS.—Mary Everett, of Fort Fairfield, Me., is said to have been born in 1812. She recently made a journey alone to the West to visit her daughter.

Mrs. Lemuel Cox, of Malden, Mass., is said to have been born in that city in June, 1812. All of her seven children are deceased, but her own health remains excellent.

TWO VENERABLE PHYSICIANS.—It is a noteworthy fact, at this commencement season, that the oldest living graduate of both Harvard and Yale is a physician. Dr. James Lloyd Wellington, of Swansea, Mass., graduated from Harvard in 1838; and Dr. David F. Atwater, of Springfield, Mass., from Yale in 1839.

NEWTON HOSPITAL TRAINING SCHOOL.—The annual graduation exercises of the Newton (Mass.) Hospital training school were held in that city on June 4. The principal address was made by Dr. Joel E. Goldthwait, of Boston, and diplomas were awarded to 21 graduating nurses.

OPEN AIR SCHOOL ON CASTLE ISLAND.—Beginning the last week in June, an open air school will be maintained through the summer on Castle Island in Boston Harbor by the Boston Dispensary, the Boston Instructive District Nursing Association, and the Boston Society for the Relief and Control of Tuberculosis. This school, which is intended as a successor to the former one at Franklin Park, is designed not for children actually tuberculous, but for those predisposed to tuberculosis, whose resistances it is hoped by this measure so to strengthen that they may become capable of successfully avoiding subsequent infection.

MILK AND BABY HYGIENE NURSES.—It is announced that of the $2000, for which an appeal was made by the Boston Milk and Baby Hygiene Association in the issue of the JOURNAL for May 28, $1000 have already been raised, and additional nurses have in consequence been assigned to the milk stations in South Boston, East Boston, and the West End. Other nurses will be assigned as soon as the remainder is subscribed.

HOSPITAL BEQUESTS.—The will of the late Nellie H. Bonney, of Haverhill, Mass., which was filed in the probate court at Salem, Mass., on June 5, contains ultimate reversionary bequests of $5000 each to the Hale Hospital, Haverhill, and the Boston Floating Hospital.

The will of the late Esther F. Emerson, of Gloucester, Mass., contains a residual reversionary bequest for the foundation of a memorial hospital at Milford, Mass.

NEW YORK NOTES.

LEGACY BY DR. BRYANT.—By the will of the late Dr. Joseph D. Bryant, professor of surgery in the University and Bellevue Hospital Medical College, a trust fund of $1,000 is established for the benefit of New York University. The directions regarding it left by Dr. Bryant were as follows: "The income of this fund shall be devoted to instilling in the minds of the senior class the principles of ethics of the American Medical Association. This bequest is made in the belief that early admonition and the implanting of preventive means to seductive inclinations or dangers is the surest method of securing ethical practice in human affairs" Upon the death or remarriage of his widow, one-seventh of Dr. Bryant's residuary estate is to be given in trust to New York University, and one-seventh in trust to the New York Academy of Medicine. One contingent bequest of $10,000 is to be devoted to opposing the efforts of anti-vivisectionists in New York State.

BELLEVUE HOSPITAL.—The present house staff of Bellevue Hospital appears to be unusually rich in musical talent. On June 7 nine of its members, for the entertainment of the patients, gave on the hospital grounds an orchestral concert which was much appreciated by an audience of more than 1,200, including Dr. Brannan, president of the board of trustees, and Drs. O'Hanlon and Fleming, the medical superintendent and assistant superintendent of the hospital.

MORTALITY FOR WEEK ENDING JUNE 6, 1914.—There were 1291 deaths and a death-rate of 12.06 per 1000 of the population reported during the past week, as against 1447 deaths and a rate of 14.05 during the corresponding week of 1913, an absolute decrease of 156 deaths and of 1.99 points in the weekly rate, which is equivalent to a relative decrease of 213 deaths.

The following causes showed material decreases: measles, scarlet fever, diarrheal diseases under five years, digestive diseases other than diarrheal, acute respiratory diseases. Those causes showing an increased mortality were diphtheria and croup, whooping cough, typhoid fever, cerebrospinal meningitis, organic heart disease and violence. The mortalities from pulmonary tuberculosis, Bright's disease and nephritis, and diseases of the nervous system, were approximately the same as those for the corresponding week of last year.

Viewed from the point of age grouping there was a tremendous decrease in the mortality among infants under one year, there being 91 less deaths reported at this age. The mortality between one and five years of age was slightly lower, there being nine less deaths at this age period; between the ages of five and sixty-five years there was a decreased mortality of 85 deaths. The only age group that showed an increased mortality was that of over sixty-five years of age, there being 29 more deaths reported.

The death-rate for the first twenty-three weeks of 1914 was 15.15 per 1000 of the population, a decrease of .21 of a point compared with the corresponding period of 1913.

LONG ISLAND COLLEGE HOSPITAL.—At the annual meeting of the Association of Alumni of Long Island College Hospital at the Polhemus Memorial Clinic, on the evening of June 9, a striking announcement was made concerning the reorganization of the institution. A fifth year medical course has been adopted and the curriculum has been entirely changed to meet modern demands. Students will be accepted from the high school upon possession of a full medical student's certificate, and they will enter the preliminary year for instruction in chemistry, physics, biology, French or German, physiology and embryology. The freshman and sophomore

years will be devoted exclusively to the laboratory branches, and the various laboratories have been equipped with the latest and best apparatus. The junior year will include clinical work in medicine and surgery and daily dispensary work, while the fifth year will be devoted entirely to bedside work. Every clinical branch will have a full quota of resident full-time instructors.

Long Island College Hospital has at this time 300 beds and there is in course of construction a large wing which will give the institution 450 beds, making it one of the largest hospitals in New York. The clinical material in the hospital will be available for the students of the medical school, and the very close connection between the hospital and the college gives the students unsurpassed opportunities for bedside instruction. There has also been a considerable change in the faculty, and this reorganization, together with the addition of several full-time instructors, will give the institution a teaching staff of decided strength.

AWARD OF LUCIEN HOWE PRIZE.—It is announced that the Lucien Howe prize of the New York State Medical Society has been awarded to Dr. Mark J. Schönberg for his research work on ocular anaphylaxis.

11. KING, J. J. *A Satisfactory Local Anesthesia for the Submucous Resection of Nasal Septum.*

1. Simon finds that a sex gland reaction, such as the Abderhalden test, may be obtained in nearly, if not all, cases of dementia precox at some stage of the disease, but that the reaction is not specific of dementia precox, as Fauser would have us believe. The author quotes a large amount of information from the literature and the paper is a well written treatise on this subject.

2. Janeway, considering the results so far reported on the treatment of cancer with radium, especially those of Wickham, makes the definite statement of its value about as follows: All operable cancers should be operated on immediately without delay. This is an absolutely fixed rule. Radium has no place in this type of growth. Radium confines its value to superficial growths, for it has been found that its more fully penetrating rays may even stimulate the growth of cancer cells situated deeply beneath those under treatment.

3. McCaskey's article is a description of refinements in technic of administration. [E. H. R.]

THE LANCET.

MAY 9, 1914.

1. ORMEROD, J. A. *The Lumleian Lectures on Some Modern Theories Concerning Hysteria. Lecture III.*
2. *ELLIOTT, T. R., AND DINGLEY, L. A. *Massive Collapse of the Lungs Following Abdominal Operation.*

3. *SWAN, R. H. J. *Tumors of the Urinary Bladder.*
4. *JEFFERSON, G. *Death from Hyperacute Streptococcal Infection (Streptiœmia) Following Radical Removal of Cervical Tuberculous Glands with Sinuses.*

7. WELCH, H. V. *A Case of Carcinoma of the Breast in a Male.*
8. VERDON, H. W. *A Note on the Aspiratory Function of the Heart.*

2. The writers have studied eleven cases of post-operative collapse of the lung and discuss this condition. Each had muco-purulent expectoration and high fever preceding the collapse, thereby closely resembling pneumonia. There is cardiac displacement toward the affected side and compensating emphysema of the sound lung. Pain and cyanosis may develop. At first there is dullness, immobility, weak breath sounds on the affected side, which later becomes bronchial. Usually, all signs vanish in two to three days, but in some cases a true pneumonia may develop. Expectorants should be given, and deep breathing encouraged.

3. Swan classifies, discusses and describes the various tumors of the bladder and remarks briefly on prognosis and treatment.

4. Jefferson describes a fatal case of operation for removal of tuberculous cervical glands and calls attention to the fact that this operation is not free from danger, particularly if discharging sinuses are present. [J. B. H.]

MAY 16, 1914.

1. WATERSTON, D. *Arris and Gale Lecture on the Development of the Heart in Man in Relation to Its Functional Activity.*

3. AULD, A. G. *Oxygen Want and the Means of Its Relief.*
4. *SHAW, B. H. *The Relation between Epilepsy and Tuberculosis.*
5. WHELAN, J. H. *Strychnine-Tuberculin Treatment of Hospital Tuberculous Cases.*
6. *LECKIE, A. J. B. *The Cutaneous Tuberculin Reaction of Von Pirquet.*

2. Russell discusses angiospasm, its cause, diagnosis, symptoms and treatment in an interesting and practical way.

4. Shaw seems to feel that epilepsy may be a manifestation of an early or latent tuberculous infection. He has found an amazingly high percentage of tuberculous infection among epileptics and is of the opinion that there must be therefore some relation between the two conditions. His remarks are interesting, but need confirmation.

6. Leckie, as a result of his investigations, concludes that the cutaneous tuberculin reaction is of no prognostic or diagnostic value, especially in adults and that cases of rheumatism give more positive results than tuberculous individuals, and that early and late reactions have no clinical significance. (These remarkable statements are interesting, if true.) [J. B. H.]

9. Meltzer, S. J. *The Present Status of Intratracheal Insufflation.*
10. Böhm, M. *Orthopedic Measures for the Children of the Berlin Parish Schools.*

3. Harttung reports a series of over sixty experiments in guinea-pigs, in which he caused an artificial hydronephrosis on one side by obstructing the ureter, and then observed the reaction of the diseased, in comparison with the well kidney, to various infections. In one set of cases he noted that after injection of living bacteria into the blood stream the uninjured kidney would show no pathological changes, while the other would have broken down in a suppurative process. The whole work emphasizes the great importance of hydronephrosis, whether congenital or acquired, in the etiology of renal infections. [R. H. M.]

10. Berezniegowski, N. *The Use of the Isolated Omentum for Control of Liver Hemorrhage. Experimental.*

1. Lick believes that early operation is indicated in all definite cases of Basedow's disease, as soon as the diagnosis is made. Thus the other organs (heart, liver, kidneys, etc.) are spared the irreparable injury which they would otherwise sustain. Operation in early stages is easier, and can be made more complete. The danger of recurrence is thereby lessened, and the exophthalmos will completely disappear. [G. G. S.]

10. *FROELICH, E. *A New Hypnotic,—Dial-Ciba.*

10. Froelich finds dial-ciba an agreeable and efficient hypnotic. One tablet of 0.1 gm. is sufficient in ordinary cases of insomnia. In nervous subjects 0.15 gm. will induce sleep of about seven hours' duration. Two to two and a half tablets are sometimes necessary. Post-hypnotic effects are less likely to occur if the drug is given moderately early in the evening. It is absorbed better if given dissolved in hot water or weak tea. [L. D. C.]

REVUE DE MÉDECINE.

APRIL, 1914.

1. *COUCHOND, P. L. *Kubisagari (Gerlier's Disease).*
2. MOLLARD, J., AND DUMAS, A. *Gallop Rhythm in the Course of and During Convalescence from Typhoid Fever.*

1. The "Maladie de Gerlier" was first met on the Franco-Swiss border. It was described as an affection, prevalent in that locality alone, presenting during the summer months periodic attacks of localized paresis. The muscles involved in the characteristic cases were those of the neck and lids, and less frequently the arms and legs. Gerlier describes the three stages graphically as follows: the first represents the "drunken man," whose unsteady gait is helped by the downcast eye; the second, the head and body are inclined to the earth, much as the peasants in Millet's Angelus; the third shows only the ptosis, so that the individual appears to sleep while standing.

In later years the same syndrome has been observed in certain of the countries of Northern Japan. Here the name kubisagari is used, because of the typical attitude of those afflicted. Miura lays especial stress upon the periodic appearance of the following symptoms: ptosis, paresis of the extensors of the neck and back, paresis of the arms, and paresis of the lips, tongue, and the muscles of deglutition.

The observations of Miura and Takemura show a wide variety of cases of this interesting, but rare and closely confined disease. The latter was able to isolate from the spinal fluid of one patient, suffering from an acute attack, a small, gram-negative micrococcus. Subcutaneous injections of this organism produced in a great majority of instances in cats symptoms directly correspondent with the human form of the disease. In only one instance could the same organism be recovered from the spinal fluid of a cat so affected. The bacteriological findings, while by no means conclusive, are encouraging and indicate the line of future work in connection with this disease. [L. H. S.]

REVUE DE CHIRURGIE.

APRIL, 1914.

1. *QUÉNU, E., AND COSTANTINI, H. *Indications for Intestinal Resection in the Radical Cure of Certain Herniae.*
2. *WALTER-SALLIS, J. *Non-Biliary Pancreatitides (Conclusion).*
3. *HARDONIN, P. *Clinical and Experimental Study on Traumatic Backward Dislocations of the Knee. (Conclusion.)*

1. The authors report a number of illustrative cases and conclude that, apart from complications, such as strangulation and gangrene, enterectomy may be indicated in herniae with a neoplastic or tuberculous content and in certain adherent herniae.

2. The writer reports 12 cases of his own observation and experience, and collects 45 others from the literature.

3. In conclusion, Hardonin summarizes a total of 79 collected cases, arranged according to his method of classification and illustrative of the types of backward knee dislocation. [R. M. G.]

Correspondence.

PARIS LETTER.

THE MEDICAL ATMOSPHERE OF THE RENAISSANCE AS PORTRAYED IN SOME EARLY FRENCH WRITERS.

II. MAÎTRE FRANÇOIS RABELAIS.
(1540–50, Circa.)

(From Our Special Correspondent.)

"Heureux le medicin qui est appelé sus la declination de la maladie!" (III.41.)

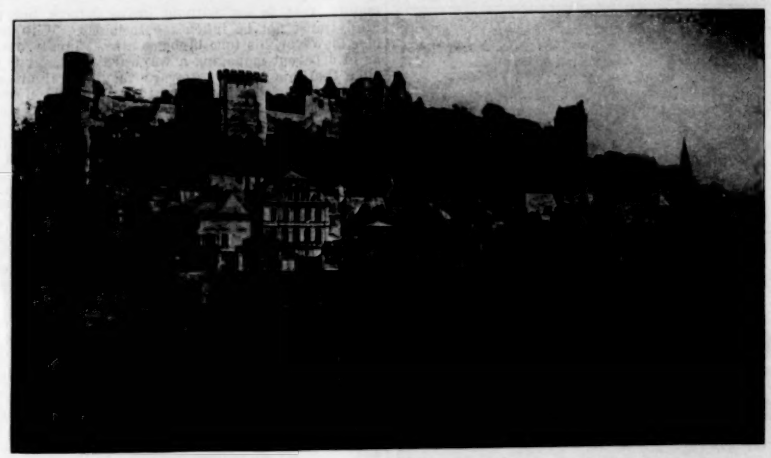
PARIS, 1914.

Mr. Editor: To undertake to write about such an intellectual colossus as Rabelais is impossible without a certain feeling of misgiving, for it is lamentable to be conscious of being unequal to one's subject, whose extent in this instance is infinite, Rabelais' range of knowledge seems, for his times, practically universal. The first fifteen years of his adult life were spent in convents, where he acquired his marvellous familiarity with the Greek and Latin classics, and an insight into the natural sciences, botany, etc., and astrology. He then laid aside the habit and undertook a round of the different universities of France, studying law, medicine and the liberal arts, ending up finally as a physician. The latter capacity led to his being attached to the embassies of various exalted personages to Italy, Rome and the Pope,—all of which ultimately gave him a breadth of view and field of experience quite out of the ordinary for his period.

Unfortunately, Rabelais is little known to the general reader. His prose is almost untranslatable, and if he is taken in the original the student is rebuffed by a style such as was never before seen in print, and by what seems, to us at least an endless amount of tedious detail. It is, I think, the common custom to look on Rabelais as a foul-mouthed, bibulous ribald. Never was there a grosser error. A man whose early education was acquired in learned and refined surroundings, whose constant frequentation was with cultivated professional men, and who was associated during his latter years with the most distinguished representatives of his country, could have had none of these characteristics. The language of his writings, is to be sure, something awful; it is strange that the very paper on which it stands does not turn red with dismay. Thus a friend of mine, a prominent divine, on inheriting an old and valuable edition of Rabelais, promptly put it in the fire in horror after only looking inside the covers! But this could never have been his natural mode of expression. It was assumed for a purpose, possibly to appeal to the masses. The speech of the people in France, even

STATUE OF RABELAIS AT CHINON.

today, is,—let us say "free," to a degree; listen to two cabbies on the street having a heart-to-heart unbosoming in a dispute, and you will have difficulty in finding anything more lurid even in Rabelais' astounding vocabulary. There is only one way of going at Rabelais,—to read him in the original, without expurgation, and to keep at him until you get quite used to his terrible style and pass through it to the riches concealed beyond. To resort to a simile that would certainly have appealed to our author, would it be rational to refrain from enjoying the contents of a bottle of rare old wine, simply because it was coated on the exterior with a thick layer of dirt, mold and cobwebs?



This remarkable confrère of ours is generally cited as the leading exponent of the art of using the most withering satire without a particle of passion or personal *animus* appearing in it,—a feat difficult above all others. Each of the liberal professions comes in for its share in turn, the Church, the Sorbonne, Medicine, and in particular Law; anything so appalling as his repeated onslaughts on his brethren of the legal profession I have never read. Yet in all of this the reader looks in vain for any evidence of concealed rancour or vengeance; he seems to have criticized and condemned purely because he saw the flaws and knew they deserved to be held up to opprobium. He appears to have been altogether ahead of his times; it would not be easy for a person, even nowadays, to take a more just view of the foibles of the first half of the 16th century.

It is in a way a consolation that of the four callings named, Rabelais is least severe on medicine; let us take this straw to our bosoms and be thankful for it such as it is! Law he simply reduced to pulp with a sledge-hammer and then cast that pulp into a furnace at white-heat. When he finished, there was nothing. His touch was that of the unflinching judge who, called on to consider a case absolutely bad in all particulars, says so in the plain and unmistakable language suited to the occasion. With the Church and the Sorbonne, on the other hand, his satire nearly approaches good-humor. He gives the impression that he is here dealing with a weak side of humanity, that is not without grave defects, but that really must not be taken too seriously. With medicine, however, his tone becomes almost kindly, joking, as of a parent managing a wayward child. It is possible that his leniency toward the medical art may be due to the fact that he considered himself in reality a physician, all of his later work being signed maître François Rabelais, docteur en medicine; but the fact remains that with one exception most of his little flings at our noble profession border rather on the joke-province than on that of satire. In the fifth book, in his vitriolic diatribe on the lawyers in the guise of the chasfourrez, he speaks of the "ignorance, impudence and imprudence of physicians, surgeons and apothecaries"; but the context here shows beyond peradventure that in all this fulmination of the Gueux-de-bien he was using the strongest terms at his command, and that since he wished to prove that the lawyers were the blackest of the black, the necessities of the case demanded that he should make his contrasts as sharply outlined as possible.

On leaving convent life for the universities he first went to Montpellier with the idea of taking up medicine, "mais il considera que l'estat estoit fascheux par trop et melancholicque, et que les medicins sentoyent les clysteres comme vieulx diables." That is more his real tone in dealing with the profession. Farther on he remarks: "Consider what a strange world this is: we entrust our souls to the theologians, who for the most part are heretics; our bodies to the physicians, who all abhor medicine and never take any; and our belongings to the lawyers who never go to law among themselves." The second phrase in this sentence Pantagruel accounts for as follows: "I can only approve of it, as I note that physicians lay so much stress on prophylaxis and precaution as regards their own health, that they stand in no need of curative treatment by means of drugs." It must be admitted that there seems a surprising amount of sound common sense in all of this, for the period.

As regards general hygiene, Rabelais is a strong partisan of having the chief meal at night, and of eating only sparingly at noon, "no more than sufficient to stay the clamours of the stomach . . . which is the only real way to live, based on good and sound medical precepts,—whatever a lot of fool doctors brought up among the Sophists may say to the contrary." So this point was in dispute even in those days! In the discussion between Frère Jean and Gargantua as to the advisability of drinking wine early in the day, the latter affirms that the practice is in complete disaccordance with medical teaching. This, however, is as good as no argument at all, in the eyes of the monk, who forthwith crushes his opponent with the following reason for not paying attention to what the doctors say: "Cent diables me saultent au corps s'il n'y a plus de vieulx hyvrognes qu'l n'a de vieulx medicins!" and he closes the discussion with "Mais, *venite apotemus!*" The jolly friar had concluded a most practical pact with his digestive organs, that will awaken feelings of envy in many a bosom, and that he unfolds in these terms: "I have arranged matters with my appetite in such a way that it always goes to rest when I do, and to this end I take the measures suitable during the day; but on the other hand it is equally ready to get up when I do."

Since we have mentioned the taking of wine, which occupies such a prominent part in all of Rabelais,—no action ever taking place without all hands first indulging in a drink,—and which has given rise to the idea that our author was a perpetual tippler, I should like to unburden myself on this point, which I have been at some pains to investigate personally, having made several trips to Rabelais' country, the Chinonais, and sampled conscientiously the different wines of the region. I do not believe that there are any more grounds for considering Rabelais as a tippler, than as a scurrilous debauchee, as mentioned in the early part of this article, and for the reasons there given; still, this unceasing introduction of wine-

THE ANCIENT TOWN AND CHATEAU OF CHINON, ON THE VIENNE IN TOURAINE.

drinking throughout his works does require some explanation.

The French tongue has two words to describe the man who enjoys food, *gourmand* for him who merely "stokes" his stomach, and *gourmet* for the eater of refined and delicate taste. Now Rabelais was a *gourmet* in drinking, what they call a *fin palais*, in connection with the fermented juice of the grape. This is apparent in many a passage, thus: "le noble pontife (evesque d'Auxerre) aymoit le bon vin, comme faict tout homme de bien"; again: "vous mesmes, monsieur le prieur, aymez boyre du mielleur. Sy faict tout homme de bien; jamais homme noble ne hayst le bon vin; c'est un apophthegme monachal"; and there is an unmistakable accent of sincerity in the Friar's exclamation: "Que Dieu est bon, qui nous donne ce bon piot!" That cry came straight from the heart. Elsewhere, in one of his inimitable scenes, he refers to wine as "eau beniste de cave." So there is no doubt that Rabelais was not above appreciating a good thing when he got it. But there remain two points to clear up: how it was that his characters stood the amount of wine they were always imbibing; and why it was that Rabelais' constant refrain is that the wine must be cool.

As regards the first question,—when you have made a thorough study of the wines of the Chinon region you soon see that though very smooth and pleasant to the palate they have no bouquet and but a low degree of alcohol; it consequently seems probable that for a person of the district, accustomed to them from birth, the amount he could imbibe would be limited purely and simply by the quantity he could hold, and that the alcoholic effect on him would be more or less nil. This would seem to afford a satisfactory explanation of the fact that Rabelais' characters never move, morning, noon, or night, without first taking a copious libation of wine. But as regards the second point, the explanation is less easy. In Book I, Chap. 6, our author says that "a man of good sense always believes what he is told and what he finds in print." Now, although some people might dispute the validity of this assertion, I followed it in Rabelais' case, and in view of his constant cry: "beuvez fraiz si faire se peut," I took his advice at the letter, although the best Chinon wine is red, and it is against all rules to drink a red wine cold. I first landed at Chinon one winter's night, Christmas eve, in fact; but encouraged by a bright, cheerful dining room, and by finding comfortable central-heating in a little French provincial inn, I decided to begin my wine investigations at once and had a bottle up straight from an icy cellar. Beuveurs, mes frères,—*never* do that! Let my experience suffice. I spent the remainder of the evening nursing a hot water bag, in the hope of thawing out that awful lump beneath my chest.

This not seeming quite according to schedule I on the next day visited the Devinière, the farm where Rabelais was born, and lunched in a neighboring tavern, where we again had a red wine, which, after sampling, we carefully warmed before the fire. Rabelais says: "O Lachryma Christi! c'est de la Devinière. O, le gentil vin blanc, ce n'est que vin de taffetas." Now the white wine of the Devinière of 450 years ago may have been all sorts of things,—that I am not prepared to dispute; but to apply such terms to the product of today, is to indulge in what the rhetoricians call hyperbole, I believe. However, this does not prevent the fact that really first-class Chinon wine is a very pleasant drink. It may possibly be that in Rabelais' day the Chinon vineyards produced chiefly a white wine, which, I need hardly say, is usually consumed cold. I am afraid that I have been somewhat lengthy on this point; but it has been one that has preoccupied me considerably. There is a final detail in Rabelais connected with eating and drinking that is new, to me at least: that pears and cheese go remarkably well together. This I had never observed.

From an anatomical standpoint I should be glad if any reader can tell me why in Rabelais the medius is so frequently called "the medical finger"; I suppose there is some very simple explanation of this fact, but I do not know it. Rabelais also raises another question that had never occurred to me: that whereas some of our senses (sight, taste) are furnished by nature with means of protection (lids, lips), others, and in particular the sense of hearing, are not, but remain open to influences from the exterior all the time. This whole passage (III. 16) is very curious. Alexander the Great, victorious in Persia, was regretting that his people in far away Macedonia would not be able to hear of his prowesses until after so long a lapse of time, when a man presented himself before him and claimed to have invented a means whereby Alexander's fellow countrymen could be informed of the great news in the re-

markably short space of five days. This idea seemed to Alexander so uncanny that he refused even to listen to the man, which Rabelais reproves: "What would it have cost him to hear and learn what the man had invented? Nature appears to me to have created our ears open not without grounds . . . so that at all times, at night, we can constantly hear, and by hearing, constantly learn; for it is the sense above all others the most apt to instruct us."

As regards insomnia Rabelais puts into the mouth of his *enfant terrible*, Frère Jean, views that are sadly unorthodox. Gargantua being quite unable to fall asleep, the Friar remarks: "personally I never sleep really well except during a sermon or at prayers. Let us commence, you and I, the seven psalms, and see whether you are not soon asleep." And beginning the first psalm they were both sound asleep by the Beati Quorum! For seasickness Rabelais advises copious libations: "They all drank the travellers' health, and all the travellers drank theirs, which was the explanation of the fact that none of the assembly became seasick." The popular remedies of the day appear to have been: to drink seawater, pure or mixed with wine, for several days before going on board; to eat quinces, lemonpeel, or take pomegranate juice; to make a long fast; or to cover the stomach with paper,—"or otherwise to follow the directions which silly physicians give to those going to sea." Perhaps when next you go on board the good ship Mauretania you may like to try some of these novel remedies?

As regards the treatment of luës, it was that of the times,—sweating and inunctions, carried to the point that the patients teeth rattled in their heads like the keys of an organ, and they foamed at the mouth with excess of saliva. But where Rabelais really becomes curious is in his views as to the frequency of this disorder. When Epistemon returns from his brief sojourn in Tartarus, and speaks of the various occupations at which its inhabitants were kept busy, he says that Pope Sixtus' duty was to administer these very inunctions. "What, said Pantagruel, do they have that disorder *there*?" "Certainly, replied Epistemon; I never saw so many cases before: there are more than a hundred million of them; for, believe me, those that do not have it in this world get it in the next."—which is not a very reassuring outlook. In another passage he refers to the first known case of luës, contracted "by not taking his wine cool in summer!" This special etiology had not yet, I think, been reported. In Book II, Chap. 33, is an account of Pantagruel's encounter with the specific catarrh connected with Neisser's micro-organism. In French this scene goes all right; but I do not quite see how to turn it into English, so inquisitive readers will have to look it up in the text. But his explanation in this connection of the properties and nature of mineral springs, is certainly orginal, if nothing else.

In addition to the possibility of an early knowledge of wireless telegraphy, darkly hinted at in the story related concerning Alexander the Great, the question arises whether our confrère Carrel is entitled to quite so much credit for the originality of his researches as is customarily accorded to him. Thus, after one of their many combats Epistemon was found dead with his head completely severed from his body. Panurge, however, was equal to this predicament, as the victim was still quite warm. Clasping the head to himself so that it should not be exposed to the wind or lose heat, he carefully washed both surfaces of section with fine white wine, powdered and anointed it, and then adjusted vein to vein, nerve to nerve, and spondyle to spondyle, so that there should be no torticollis. He next placed 15-16 sutures all around, to prevent its falling off again, and ended up by an application of what he called "resuscitating ointment." Wherupon the patient breathed, opened his eyes, etc., and was given a big draught of white wine and burnt sugar,—naturally; it would have been strange if they had not introduced some more white wine into the scene somewhere, all hands having full right to refreshments after such a remarkable operation as that!

The list of Rabelais' curious views on medicine is hereby by no means exhausted, but fear that the reader's patience *is;* so I will close by the passage in which he refers to the question of physician's fees. His description of this scene is a pearl, but it will have to be given in the original: "puys s'approcha de luy et luy mist en main sans mot dire quatre nobles à la rose. Rondibilis les print très bien, puis luy dist en effroy, comme indigné: Hé, Hé, Hé, Monseiur, il ne falloit rien. Grand mercy toutesfoys. De meschantes gens jamais je ne prens rien. Rien jamais des gens de bien je ne refuse. Je suys tousjours à vostre commendement.—En poyant, dist Panurge? Cela s'entend, respondit Rondibilis!"

And with this shrewd piece of observation we will end this all too summary sketch of this, one of the most remarkable men our profession has ever included in its ranks.

"Q."

UNITED STATES CIVIL-SERVICE EXAMINATION.

ASSISTANT EPIDEMIOLOGIST, MALE.

July 6, 1914.

The United States Civil Service Commission announces an open competitive examination for assistant epidemiologist, for men only. From the register of eligibles resulting from this examination certification will be made to fill vacancies in this position in the Public-Health Service, at salaries ranging from $2000 to $2500 a year, and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion.

The duties of this position will be to conduct laboratory studies of disease, to make epidemiological surveys, to determine the prevalence and causation of epidemics, and to recommend measures to prevent and control outbreaks of disease.

It is desired to secure persons thoroughly competent in the various branches of sanitary bacteriology, and especially in isolating the typhoid bacillus from infected persons and materials.

An educational training equivalent to that required for graduation from a medical school or college of recognized standing, and at least three years' experience in epidemiological work under Federal, State, or local authorities, and experience in laboratory technic, especially in regard to tyhoid fever, are prerequisites for consideration for this position.

Applicants must have reached their twenty-third but not their fortieth birthday on the date of the examination.

This examination is open to all men who are citizens of the United States and who meet the requirements.

Persons who meet the requirements and desire this examination should at once apply for Form 304, and special form, stating the title of the examination for which the forms are desired, to the United States Civil Service Commission, Washington, D. C.; the Secretary of the United States Civil Service Board, Post Office, Boston, Mass.; Philadelphia, Pa.; Atlanta, Ga.; Cincinnati, Ohio; Chicago, Ill.; St. Paul, Minn.; Seattle, Wash.; San Francisco, Cal.; Customhouse, New York, N. Y.; New Orleans, La.; Honolulu, Hawaii; Old Customhouse, St. Louis, Mo.; or to the Chairman of the Porto Rican Civil Service Commis-

sion, San Juan, P. R. No application will be accepted unless properly executed, excluding the medical certificate, and filed with the Commission at Washington, with the material required, prior to the hour of closing business on July 6, 1914. The exact title of the examination as given at the head of this announcement should be stated in the application form.

BACTERIOLOGIST (MALE).

July 8, 1914.

The United States Civil Service Commission announces an open competitive examination for bacteriologist, for men only, on July 8, 1914. From the register of eligibles resulting from this examination certification will be made to fill vacancies in this position at salaries ranging from $1200 to $2000 a year, in the Bureau of Chemistry Department of Agriculture, for duty both in Washington, D. C., and in the field, and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion.

The duties of this position will be to examine bacteriologically food products which are subject to the food and drugs act in order to determine their sanitary condition.

An educational training equivalent to that required for a bachelor's degree or an M.D. degree from a college or university of recognized standing, including at least two years' training in bacteriology, is a prerequisite for consideration for this position.

Applicants must have reached their twenty-first but not their fortieth birthday on the date of the examination.

Applicants for this examination may be examined at any place at which it is held, regardless of their place of residence; but under an act of Congress only those who are examined in the State or Territory in which they reside and who have been actually domiciled in such State or Territory for at least one year previous to the date of the examination, will be eligible for appointment to a position in the apportioned service in Washington, D. C.

This examination is open to all men who are citizens of the United States and who meet the requirements.

Persons who meet the requirements and desire this examination should at once apply for application Form 1312, stating the title of the examination for which the form is desired, to the United States Civil Service Commission, Washington, D. C. No application will be accepted unless properly executed, excluding the medical certificate, and filed with the Commission in Washington in time to arrange for the examination at the place selected by the applicant. The exact title of the examination as given at the head of this announcement should be stated in the application form.

SOCIETY NOTICES.

AMERICAN PROCTOLOGIC SOCIETY.—The sixteenth annual meeting of the American Proctologic Society will be held at Atlantic City, N. J., on June 22 and 23. Executive Council meets 11 A.M. First Regular Session at 2 P.M. Annual Address of the President—subject: "The Future of Procto-Enterology," Dr. Joseph M. Mathews, Louisville, Ky. A program of 23 papers has been arranged.

ALFRED J. ZOBEL, M.D., *Secretary.*

San Francisco, Cal.

AMERICAN MEDICAL EDITORS' ASSOCIATION.—The forty-fifth annual meeting of the American Medical Editors' Association will be held at Atlantic City, N. J., on June 22, 1914, at 9 A.M. A literary program of 14 papers has been arranged. The dinner of the Association will be on Tuesday, June 23, at 7. P.M.

JOSEPH MACDONALD, JR., M.D., *Secretary.*

New York.

AMERICAN ASSOCIATION OF MEDICAL EXAMINERS.—The fourteenth annual meeting of the American Association of Medical Examiners will be held June 22, 1914, at Atlantic City, N. J. Hotel Dennis will be headquarters and meeting place.

APPOINTMENTS.

HARVARD UNIVERSITY. — *Dr. Robert Williamson Lovett* has been appointed professor of orthopedic surgery, and *Dr. Roger Irving Lee* professor of hygiene.

RECENT DEATHS.

DR. FRANK BISHOP HARRINGTON died at Brookline, June 8, 1914, aged 59 years. He had been a Councilor of The Massachusetts Medical Society since 1910 and was president of the Suffolk District Medical Society in 1911 and 1912

DR. JAMES A. BLAKE, of Brooklyn, N. Y., died from cardiac disease on June 9, in his 72d year. He was born in Lansingburgh, N. Y., and was graduated from the Albany Medical College in 1868 and the College of Physicians and Surgeons, New York, in 1869. For a number of years he was on the visiting staff of the Manhattan Eye, Ear and Throat Hospital. His son, Dr. James Eddy Blake, is a well-known radiographer in Brooklyn.

ANAL AND RECTAL GROWTHS OF BENIGN OR DOUBTFUL CHARACTER.*

By T. Chittenden Hill, M.D., Boston,

Instructor in Diseases of the Rectum, Harvard Graduate School of Medicine; Surgeon to the Rectal Department of the Boston Dispensary; Surgeon to the Rectal Department of the Mt. Sinai Hospital.

In a series of 3000 rectal cases which I reported at the last meeting of the American Proctologic society at Minneapolis, there were but 49 cases of benign growths and some of these it was almost stretching a point to classify as tumors so small were they in size. In fact in this series the innocent tumors were quite overshadowed by the cancer cases of which there were 76. Hence, it will be seen, that the subject under discussion this evening cannot be considered a common one. Our interest in these benign growths would indeed be small were it not for the difficulties in diagnosis which occasionally arise in some of the border line cases.

It may be said at the outset, that as ordinarily seen, the great majority of malignant as well as benign tumors of the rectum are characteristic and that their correct diagnosis is easily made. But in recent years the general practioner has begun to recognize the earlier symptoms of new growths and insists on a more thorough local examination in such accessible cavities as the rectum, with the result that more patients are now seen in an early stage, when the exact nature of the lesion is not by any means so apparent.

The two step operation, that is, first removing a specimen for microscopic investigation and later performing a radical operation, in case the growth is found to be malignant, is not now approved by some excellent authorities. They claim the probability of a cure is, thereby, greatly reduced and the statistics of Bloodgood on this point are convincing.

Although, as a rule, it is easy to differentiate the benign from the malignant, still, the number of non-malignant lesions which come under our observation with all the clinical appearances of malignancy, and *vice versa*, are frequent enough to make it worth while to study them most carefully. And when we take into account the formidable, mutilating operation with its high immediate mortality (30-40%) and small percentage of authentic cures (10-15%) to be undertaken in the one instance and the simple procedure necessary for relief in the other, the problem of diagnosis becomes a very important one.

It is no way comparable with cancer of the breast, for instance, in which a complete amputation has been performed for a benign tumor. Excellent authorities sanction the practice of treating doubtful breast lesions as malignant, and Bloodgood states that in experienced hands 10% of the complete operations are done on benign cases. It may be a deforming operation to do more than is needed for mammary growths, but, in the case of the rectum there is not alone mutilation but serious impairment of function as well, a consideration which I believe should lead us to exhaust every means of diagnosis before undertaking a radical operation.

It is not my purpose to review the literature of this subject, nor would it interest you for me to attempt a complete discussion of the varieties, symptoms, diagnosis and treatment of benign tumors of the rectum since you can acquire this information much easier and far better from the text books at your disposal. I shall, therefore, simply present to you some of the problems that have come under my personal observation, not alone of benign neoplasms of the anus and rectum, but of some inflammatory conditions that assumed the clinical appearance of malignancy.

In Mumford's book, "100 Surgical Problems," case 93, is of interest in this connection, as it illustrates the perplexity of three eminent surgeons over what turned out to be an abscess. After digital examination Dr. Mumford was in doubt as to the nature of a mass he could feel high up in the "posterior rectal region and obstructing the lumen of the bowel." The remainder of the history I quote directly from the book. "The next day Dr. M. H. Richardson saw the man with me, and we examined him carefully under ether anesthesia. We found the condition much as I have described it. A mass upon the posterior aspect of the rectum impinged upon that organ, apparently involving the mucosa; fixed, in extent the width of two fingers, and admitting a proctoscope with difficulty beyond it. The mucosa over the swelling was eroded and sloughy in appearance. To both of us it seemed highly probable that the mass was malignant but we were not altogether satisfied with that conclusion. For the next three or four days the patient failed perceptibly; his appetite vanished; he became extremely cachectic in appearance; his pulse ran up and down in an uncertain fashion, and he carried a temperature between 99 and 102. On the 12th of March (4 days later) we decided on a more extensive investigation, and called as an additional consultant Dr. J. C. Warren. After the patient was etherized my consultants asked me first to dilate the sphincter and to explore the rectum, while they looked on with great interest. On dilating the sphincter and introducing my finger cautiously into the bowel, I encountered

* Read before the Manchester, N. H., Medical Society, March 20, 1914.

almost at once the tumor, which seemed to be increased considerably in size and to be softer. As I endeavored to push past it, it suddenly ruptured, allowing the discharge of nearly half a pint of malodorous pus. The diagnosis, accordingly, was settled; we were dealing with a simple case of periproctitis with abscess."

This case was instructive and similar in many respects to several that I have met, where an abscess develops in the cellular space between the rectum and sacrum above the levator ani. As the suppurative process goes on the rectal wall is crowded into the lumen of the bowel. The infiltration of the surrounding tissue and bowel coats at first causes the mass to feel indurated and irregular and resemble very closely the sensation imparted to the finger in malignancy. A little later, however, the mass becomes soft and boggy and fluctuation is perceptible, when all doubt as to its nature is removed.

The cases in which I have experienced any serious difficulty in making a differential diagnosis have not been acute abscesses but certain blind internal fistulae associated with induration along their tracks. At first thought the diagnosis would seem to be simple, as it is in the ordinary submucous fistula, but, when a sinus occupies the pelvi-rectal space outside the bowel, the irregular outline of the induration occasionally found may very closely resemble carcinoma.

The following case illustrates this point and was for a time very puzzling.

CASE 1. Mr. G., a business man, 57 years of age, was referred to me March 17, 1911, by Dr. George W. Gay, of Boston, who had successfully operated upon him for a large fistula twenty years previously, after which he had enjoyed excellent health up to a few months before coming under my care. He seemed a fairly vigorous, wiry individual of good color, but said he had lost ten pounds during the past six months. This, he stated, was the duration of his present illness, which began with a slight discharge about the anus that still persisted. There was neither rectal pain or hemorrhage, but he felt that he was growing weak, had but very little appetite and was inconvenienced more or less with indigestion. He had nothing further of importance to relate, and his heart, lungs and urine were found to be normal.

Rectal Examination. On the right side of the anus there was an extensive cicatrix of his former fistula operation with a retracted orifice, as is frequently seen in these cases. Posteriorly there was an opening between the sphincters that admitted a probe for a distance of one inch. On digital exploration, an oval mass about the size of a halved walnut, could be felt on the posterior rectal wall, slightly to the left of the median line. It felt a bit boggy and the mucous membrane was slightly movable over it. It was not nodular, but was rather irregular in outline, and at its upper extremity there was a small indurated area. A polypoid growth the size of the end of a lead pencil lay near by.

Although there was nothing absolutely definite about this mass, there was, as I find in my notes, a "suspicious feel" and I arranged for a consultation with Dr. Gay the next day. At this examination the swelling seemed less indurated, and we agreed that there was little likelihood of malignancy. As it did not seem that any procedure, short of an operation, would cure his local trouble, Dr. Gay recommended a Southern trip, together with some constitutional treatment. He came to me again five weeks later, with a note from Dr. Gay asking me to do "whatever I thought best." His vacation in the South had not improved matters. He did not look as well as when I last saw him, and called attention to his further loss of weight which he stated now amounted to 20 pounds, and judging by the loose fit of his clothing about the waist it may possibly have been more.

At this visit the mass in the rectum felt distinctly larger, but in other respects about the same as at the first examination. I urged operation and explained the element of doubt about the nature of the growth, whereupon he gave his consent to excision if it seemed necessary when under ether. Dr. Gay, who saw him at this time, wrote me as follows: "Mr. J. was in this morning. That growth feels somewhat larger than it did a month ago and the upper edge is more defined to my touch. It is soft more like a sarcoma than a carcinoma. In view of the loss of flesh and strength, I agree with you that he should have ether and all should be in readinesss for removal of the growth, if the ultimate examination confirms the present one. I have urged immediate action, irrespective of any business engagements."

At operation a few days later, with the patient completely anesthetized, so that one could thoroughly palpate the mass, get well above it and exert firm pressure, the hard irregular character of the growth disappeared, and it became almost soft and pulpy under manipulation. It was, therefore, perfectly evident that we were dealing with an inflammatory condition about the track of a deep fistula.

A director was inserted into the small posterior opening for a distance of one inch, where resistance was met, and, with the director as a guide, I carried the incision a little beyond and to the right of the coccyx. This sort of a case, in my judgment, needs particularly good drainage, and for this reason should be freely incised. With the wound well retracted, an opening was found through which the director was easily passed to the mass felt in the rectum. After dividing two constricting bands, the finger was readily inserted into a fair-sized cavity filled with cheesy, sebaceous material, made up of retained blood and pus, which was removed with a curette, whereupon the tumor entirely disappeared. There was considerable lateral burrowing, especially on the left side, that had to be dealt with, as well as a sinus which extended over an inch above the mass, making the entire track nearly five inches in length. After irrigation, two good sized rubber drainage tubes were passed to the upper part of the wound, and snugly packed about with gauze. A rubber tube was also inserted in the rectum to overcome any discomfort that might arise from the retention of flatus.

One lesson to be learned from this case is the far different aspect a mass in the rectum

often assumes when the patient is completely relaxed under a general anaesthetic. I have not found the proctoscope of much assistance in questionable cases, although it is perfectly satisfactory in diagnosing the more typical growths above the reach of the finger.

In the case of Mr. J. there were three possible diagnoses:—(1) A gummatous growth, which is very rare in the rectum, was ruled out because he had never had syphilis, nor were there any signs of the disease to be found. (2) Tubercular ulceration may be mistaken for carcinoma, when there is a surrounding chronic inflammatory thickening associated with considerable tumefaction. In this case there was no ulceration of the mucosa, and tuberculosis was therefore not seriously considered. (3) The only question left to decide was, is this a fistula outside the gut, or a malignant growth. The irregular outline and induration suggested malignancy, but the fact that the mucous membrane over the swelling was smooth and intact, and there was already a discharging sinus, pointed to the inflammatory nature of the disease.

A second case, in which the diagnosis was deferred for some time, proved to be an adeno-carcinoma.

Case 2. This patient, Mrs. A., 40 years of age, was referred by Dr. Frank B. Brown of Dorchester, for a fistula of twenty years' standing. She had been operated upon three or four times without permanent benefit, and she stated that she had never considered herself cured at any time, as there had always been some discharge of pus about the anus. Her general health was very good. She was a small but well developed woman, of good color, and her weight was about normal.

On careful rectal examination the opening of the fistula was detected in the posterior mid-line, between the sphincters, in much the same location as the preceding case. There was no external opening, but back of the anal orifice, and extending into the right ischio-rectal fossa, could be felt an indurated track about one and a half inches in length. Pressure on this caused some pain and the escape of several drops of pus from the internal opening.

I sent this patient to a private hospital, where I thoroughly incised the fistula, which was found to be rather extensive and complicated by numerous burrowing tracks leading from the main sinus. There was much cicatricial tissue, partly caused by her former operations, which was also removed. Nothing that would in any way bear on the future history of this case was noted at operation. I am positive there was no induration about the internal opening at this time, or for some time later.

Although two of her former operations had been performed by a surgeon of large experience, I attributed the several failures to cure this fistula to a condition seldom recognized by the general surgeon, and to which attention was called by Brick of Philadelphia a few years ago. Blind internal fistulae of the posterior commissure are frequently very troublesome if some of the fibres of the external sphincter are not cut at right angles, so as to put the muscle completely at rest. Simply incising the external sphincter in a posterior direction is insufficient, because it merely separates the fibres, most of which, it will be recalled, have a Y-shaped arrangement as they pass behind the anus, and thence backward for attachment to the coccyx. The difficulty often experienced in this type of fistula is that the sinus apparently does well at first, but the discharge does not altogether cease, and it will be found that a small pocket-like ulcer persists at the anorectal line, which repeated curettings and applications seem to have little effect upon. Even another incision in an antero-posterior direction, which only separates the fibres again, will have no better effect, but after laterally cutting a few muscle fibres, healing is prompt.

My operation was in January, 1909. The wound healed slowly, and in about two months closed entirely, except for a small ulcer in the posterior mid-line, much like the one just described, notwithstanding the fact that the precaution had been taken to incise the muscle, as recommended by Brick. It was a small round ulcer, about one-eighth of an inch in diameter, and caused the patient no discomfort. I then believed it would disappear with or without treatment, but as she was more or less conscious at times of a little moisture of the parts, I saw her at monthly intervals from then on to the following January, when a small indurated area the size of a pea appeared at the upper edge of the ulcer. A probe was passed under this little swelling, without any pressure, and this fact seemed to afford a very reasonable explanation of the delayed healing of the ulcer. Feeling somewhat chagrined that a small submucous fistula had escaped my notice so long, I proceeded to incise it, under local anesthesia, before she got off the table. But the induration did not disappear, and slowly, during the next six weeks, extended a little higher, when it was an inch in length, oval in outline, and covered with smooth, firmly adherent mucous membrane.

A second operation was advised, and as the mass seemed to me a suspicious one, I called in consultation Dr. F. P. Williams, my associate at the Boston Dispensary. Under ether the growth felt hard and rather irregular, and was suggestive, to say the least, of malignancy, but as a grooved director easily passed to the top of the swelling, it was pushed through and the overlying tissue divided. A specimen was sent to Dr. Timothy Leary, who reported simple adenoma.

Even with this comforting assurance the induration and swelling did not subside as would be expected in either a benign growth or an inflammatory condition. It rather seemed to be growing larger and more indurated.

Dr. James P. Tuttle of New York came over a few days later, while she was still in the hospital, and saw her. He was quite positive the growth was malignant, and I was now very willing to concur with him in this diagnosis. A perineal excision was performed, removing five inches of the rectum. The report on this specimen, rendered by the same pathologist, was adeno-carcinoma. Mrs. A. lived four years after this, but finally succumbed to a local recurrence.

The influence of syphilis in the production of fistula is an unsettled question. It has, however, long been recognized that certain simple inflammatory fistulae in syphilitic subjects do not get along well, unless anti-syphilitic

treatment is instituted either before or in conjunction with operative measures.

The following case, the most extensive fistula I have ever seen, was sent me in December, 1911, by Dr. Chas. M. Whitney, of Boston, who asked my opinion as to its malignancy. Salvarsan had been administered three times, by Dr. Whitney, for the rectal condition, and I believe this had much to do with the rapid healing that followed operation.

CASE 3. This patient was a man from Providence, R. I., who gave his age as 46, but looked 15 years older. He appeared much debilitated, and said he had lost 20 pounds during the preceding year. He had contracted syphilis in 1893, and some time during the same year an ischio-rectal abscess occurred on the left side, which was incised under ether. Following this there was very little, if any, discharge noted until 1901, when it reappeared, and had since caused him much annoyance. He had for some time been compelled to wear a large anal pad to protect his clothing from the rectal discharges. He was unable to sit with any degree of comfort. He stated that a severe burning sensation in the rectum came on about one-half hour after stool, and lasted for several hours. The discharge was profuse, at times yellowish and at other times watery.

Examination revealed a most extensive "watering pot" fistula. I was able to make out eighteen external openings, which were scattered all about within a radius of five inches from the rectum. The anal orifice was made out with difficulty, as it was occluded by three irregular wedge-shaped masses of extreme hardness, and larger than one's thumb. The skin of this region, including the nates and cruro-scrotal fold, was of a coppery red color for the most part, but interspersed here and there with shiny tense areas. The whole peri-anal region was bathed with foul-smelling pus, which could be seen escaping from many of the openings. A "malignant looking mass" describes it very well.

I completely incised this fistula at one sitting, and there was but little shock following the operation. Much of the lateral burrowing was subcutaneous, with the skin considerably undermined. It was not very deep, except posteriorly, where the track which connected the two ischio-rectal fossae extended rather high as it passed beneath the ano-coccygeal ligament. With all the external openings there was but one internal one, and that of only moderate size, situated at the interval between the sphincters, in the mid-line posteriorly.

The most remarkable thing about this fistula was the extreme induration of the tissues. Incision seemed very much like cutting cartilage, and the structures were so firm that it was difficult to spread apart the incised tracks sufficiently to explore them.

The post-operative history was uneventful. Healing progressed very rapidly, and he left the hospital seven weeks later. Dr. V. L. Fitzgerald of Providence very kindly looked after him for about six weeks longer, when healing was complete. He put on weight fast, and is now in excellent health.

The major portion of benign growths of the rectum are the adenomas or glandular polyps. They are found most frequently in children, and give rise to repeated rectal hemorrhages. In most instances, owing to the constant downward force exerted by the feces and peristalsis, the pedicle is torn away eventually, and the growth passed spontaneously. When discovered in children, however, it is best to remove them at once. When these growths are met with in adult life, they exhibit a tendency to undergo carcinomatous degeneration. For this reason a careful microscopic examination should be made of them at the time of removal, and should there be any uncertainty in the pathological findings, the patient should be examined at regular intervals for signs of induration. Occasionally, some of these cases either from mechanical irritation, infective processes, or ulceration in the immediate neighborhood, closely resemble and may be mistaken for cancer.

CASE 4. A man, 29 years of age, sent me in November, 1911, by Dr. John H. Cunningham, of Boston, was a case of this kind. Dr. Cuningham first noticed the rectal growth while examining his prostate. His history was that eight years before, while living in New York, he first noticed that he was passing mucous per rectum. He then consulted his physician, who diagnosed his ailment as catarrh of the bowel, and treated him accordingly. Ever since then he had passed more or less mucus. For the past four years there had, occasionally, been blood as well. At times the bleeding had been rather profuse, but ordinarily only small amounts were observed.

Upon passing the finger into the rectum, a tumor, the size of a cherry, could be felt on the anterior wall just above the prostate. An indurated, slightly elevated track extended one inch below this. Through the proctoscope the appearance was spongy, bright red and lobulated. There was considerable superficial ulceration in the immediate vicinity of the growth, and it would bleed readily wherever touched. The mucous membrane above was smooth and normal. The question of malignancy may well be raised in a case of this kind. Dr. Cunningham inclined to this view, and accordingly the patient was sent to a private hospital and prepared for a radical operation. My own opinion expressed at the time was that it was benign, which conclusion was based largely on a former experience in a very similar case. It should be remembered, however, that no matter how great one's experience, one's judgment is liable at any time to be reversed by the microscope.

At operation, with the patient fully etherized, it seemed very improbable that the tumor was malignant. After the sphincters were thoroughly dilated, I was able to remove it without much difficulty, by making traction with a clamp attached to the mucous membrane below. Dr. Felix H. Adler, assistant in pathology at Harvard, and a friend of the patient as well, was present at the operation, and reported later that it was a benign growth. This was a happy outcome for the patient, as he had been prepared for the worst.

Villous tumor of the rectum is very uncommon, and but few cases have been recorded in medical literature. The chief point of interest about them is that they show a marked tend-

ency to undergo malignant degeneration. A case of this kind I reported before the American Proctologic Society in 1910, in some detail.

Case 5. This patient was a woman, 40 years of age, referred by Dr. J. H. Vaughn, of Everett, Mass., in 1907. She was well nourished, weight about normal, anemic with sallow complexion, but otherwise in good health. She had been subject to rectal hemorrhages for six years. During the year previous to my seeing her, the hemorrhages had become more profuse, and a mass always protruded from anus during defecation, and even after slight exertion, as when walking. It was necessary for her to resort to the toilet several times during the day, and to get up two or three times at night, when she would pass half a cupful of blood-stained mucus; also she was annoyed by the escape of mucus with flatus. For two months tenesmus had been present nearly all the time.

Digital examination of the rectum revealed a slippery growth with a band-like pedicle, one inch wide, attached obliquely two inches above the anus. By careful manipulation I was able to bring outside the anal orifice a lobulated cauliflower-like growth the size and shape of a large English walnut, from which there was a gentle oozing of blood while it was held outside the sphincters.

A few days later I removed this tumor under local anesthesia, at the home of the patient. The sphincters first were infiltrated with a quarter of 1% cocaine, and fairly well dilated. The pedicle was next infiltrated and clamped about half an inch from the margin of the tumor. It was then ligated in three sections, and the tumor removed. Over seven years have now elapsed with no sign of recurrence.

One of the most unusual growths ever encountered in the rectum is the myoma. It has been termed by Miles of London, a "pathological curiosity." They arise from the muscular coat and assume a nodular form, supplied with a pedicle, as a rule, but sometimes exist as broad tumors in the muscular wall of the gut without a pedicle. Tuttle cites only five cases in medical literature, and goes on to state that "these tumors are quite rare, and it is impossible to determine their nature without a thorough microscopic examination. If they are small and confined to the rectal wall the hard, nodular surface may frequently lead one to the diagnosis of schirrhus cancer."

Case 6. The only specimen of this kind I have ever seen was distinctly benign, and was removed from a man, 36 years of age, who came to my clinic at the Mt. Sinai Hospital. His rectal symptoms had existed for four years, and most important was a gradually increasing, obstinate constipation. He had at last arrived at such a state that he was unable to have any dejections in a normal manner, but relied mainly on frequent enemata in conjunction with the daily use of strong cathartics. There was an uncomfortable sensation in the rectum much of the time. He was in the habit of going to the toilet five or six times daily, but was only able to pass small particles of feces.

When in a recumbent posture he was comparatively comfortable, and at night he was free from the teasing tenesmus. At irregular intervals he was subject to small hemorrhages.

One of the remarkable features about this case was the loss of weight, stated by the patient to be fully thirty pounds. This without much doubt was due entirely to the large quantities of pills and Epsom salts he was continually taking.

A digital examination of this man was a very interesting procedure. On the occasions when he had secured the best results from the laxatives and enemata the rectum felt perfectly normal as high as one could reach, but when the gut above was more or less filled with fecal matter, a large smooth tumor, which felt much like uterine tissue, could be easily located just above the sphincters. With the finger hooked about the growth, and the patient exerting some effort at expulsion, a portion of it could be seen at the anal orifice.

At operation, over two years ago, the sphincters were thoroughly divulsed, and a large, smooth, irregular shaped mass was delivered outside the anus with some difficulty. The pedicle was rather fan-shaped, and wiry, muscular tissue could be plainly felt in it. The attachment was nearly four inches above the anus, on the anterior wall of the rectum. After transfixion and ligation, I removed the tumor with scissors.

The growth was shaped somewhat like a mushroom. Its dimensions, as measured soon after removal, were $3\frac{1}{2} \times 2\frac{1}{2} \times 2$ inches. It was found to consist essentially of spindle shaped cells, arranged in bundles, with their long axis parallel to one another. These cells were regarded as more or less well formed unstriped muscle fibre, and the tumor was identified as a pure myoma by Dr. J. H. Wright, pathologist at the Massachusetts General Hospital.

As stated at the beginning of this paper, the vast majority of benign tumors of the rectum are easily recognized. The two most common varieties are the adenoid and the fribroid polyps. They may arise from any part of the rectum, but are generally found in the lower two inches. Their presence is generally undetected until the pedicle has stretched sufficiently for them to protrude at the anal orifice during defecation. When found, I believe that, as a prophylactic measure, they should always be removed even if causing no discomfort and of course submitted to examination for possible malignancy.

Operative removal is simple and in most cases can be done under local anaesthesia. The growth should be hooked down with the finger or instruments and the pedicle infiltrated with a weak solution of cocaine and clamped with a suitable pair of forceps as close as may be to its attachment to the rectal wall. A linen or silk ligature is next applied on the proximal side of the clamp, or, if broad, the pedicle is transfixed with it and it is tied in sections. The growth is then cut away on the distal side of the clamp, which is removed, and in due time the ligature sloughs away.

When more than one or two polypoid or semi-sessile growths present to the examining finger in the rectum, and particularly if they

are rather higher than the zone of ordinary occurrence of single growths, and there is an associated history of diarrhoeal and mucoid discharges, one must at once consider the possibility of multiple adenomata, a most serious condition, rarely or never met or diagnosed by most physicians. When the growths are numerous and close together the feeling is distinctly like malignancy, and only by means of the proctoscope or sigmoidoscope can a certain diagnosis be made. These growths may, and usually do, occupy the major portion of the large bowel, bleed easily and may be soft or dense according to the amount of contained glandular or fibrous structure. They are very prone to malignant degeneration, and because one tumor is removed and found not to have been so transformed, one has no right to infer that it has not ocurred in others.

Medical treatment of this disease is largely palliative. A few cures have been reported from the employment of lavage of the large intestine but such instances must rather be regarded as symptomatic cures, for it is hard to understand how the tumors can be made to entirely disappear in this way. It may be that the origin of the trouble is some infective process, little understood, which is relieved by keeping the parts clean.

The surgical treatment involves the establishment of a temporary or permanent cecostomy or ileostomy followed by irrigation. Colectomy is not to be considered and ileosigmoidostomy is unwise

The only case of multiple adenomata I have ever seen came to the Boston Dispensary a few years ago. His record is very incomplete as he could not speak English and unfortunately never returned after the first visit. He was an Italian laborer, 40 years of age, much debilitated and evidently a very sick man. He complained chiefly of abdominal pains and copious diarrhoea (10 to 20 dejections daily) and the passage of blood and mucus.

The rectum and sigmoid, as far as the proctoscope was passed, about ten inches, was thickly studded with multiple adenomata.

I have presented this paper to you tonight with personal cases described in detail because they seemed to me to present certain problems of diagnosis and treatment of more than ordinary interest, unusual cases perhaps, yet such as might present themselves to any of you at any time.

Cases of Infectious diseases reported to the Boston Board of Health for the week ending June 16, 1914: Diphtheria 39, of which 4 were non-residents; scarlatina 60, of which 11 were non-residents; typhoid fever 4; measles 131, of which 3 were non-residents. The death-rate of the reported deaths for the week was 15.56.

BACK PAIN AND ITS DIAGNOSIS.

A STUDY OF A SERIES OF CASES.

BY HARRY PLATT, M.D. (LOND.), F.R.C.S. (ENGLAND), MANCHESTER, ENGLAND.

[From the Orthopedic Clinic, Massachusetts General Hospital, Boston.]

ONE of the commonest types of case seen in the orthopedic out-patient department of the hospital is the adult patient who complains of pain in the lower back. With a view to ascertaining the relative frequency of the varied pathological conditions causing this prominent symptom, I undertook the investigation of some forty cases chosen as far as possible consecutively from the out-patient clinic. In thirty-two of these it was possible to make a fairly detailed examination of the conditions present, and it is chiefly from a study of this series that my conclusions have been drawn.

The number of cases is unfortunately small, but they presented many features which were extremely suggestive. My special quest was to determine, if possible, how far lesions of the sacro-iliac and lumbo-sacral regions dominated the mass of lame backs coming for treatment. These investigations embraced a fair proportion of the lame backs seen in the clinic over a period of three months.

Since the classical paper of Goldthwait and Osgood in 1905[1] many studies have been made on these problems by American authors,[2] but in Europe and more especially in England, practically no attention has been paid to this important section of orthopedic surgery. The subject has come dangerously near being a well-worn one in this county, and it is very important to approach it with an open mind, preferably with a healthy scepticism.

All the thirty-two cases of the present series were of the male sex; for various reasons I did not include the few female cases I was able to see in the clinic. There are fundamental differences in the structure and functions of the sacro-iliac articulations in the two sexes, and I venture to suggest that in much that has been written on lesions of these joints, the part played by the sex distinctions has not been as fully emphasized as its importance warrants.

The thirty-two lame backs of this series group themselves into the following classes:

	CASES.
Sacro-iliac strain	12
Hypertrophic arthritis of lumbar spine	7
Postural back strain	4
Lumbo-sacral strain	3
Spondylolisthesis	2
Lumbar caries	2
Fracture transverse process, 3d and 4th lumbar vertebra	1
Infectious arthritis, lumbar spine and sacro-iliac joint (Neisser origin)	1

The outstanding complaint of all these patients was pain in the lower back, in some instances associated with pain of the sciatic type. There was no case of true sciatica or lumbago in this series; and I did not see any such case amongst a good many other back cases in the clinic during a three-months' period, although especially on the lookout for them. The comparative variety of these two so-called every-day complaints is fully appreciated by orthopedic surgeons, but not by the profession in general.

We may now proceed to a more detailed analysis of the various groups, omitting any reference to the last three, which presented no particularly important features.

SPONDYLOLISTHESIS.

The occurrence of two cases of this condition, in not a small list, may be purely fortuitous, but it is quite certain that such cases are by no means rare. A good many years ago Lane[3] pointed out the fact that spondylolisthesis was not uncommon amongst the laboring classes; in coal heavers he regarded it as almost a normal condition. Some believe the separation between pedical and lamina of the fifth lumbar vertebra to be an acquired deformity, absorption of the pedical having resulted from long continued pressure. Turner has shown that in 5% of subjects, there is a congenital lack of fusion between laminae and pedicles of this vertebra. In a given case of spondylolisthesis, it is practically impossible to determine, by skiagrams, whether such a separation is of the congenital or acquired type. When the separation exists, the body of the vertebra alone slips downward and forward, leaving the neural arch in situ. Goldthwait[4] has described how spondylolisthesis may arise where there is no solution of continuity between neural arch and body; in such examples owing to variations in shape and facing of the superior articular processes of the first sacral segment, unlocking takes place and forward sliding of the fifth lumbar is formed. Here the whole vertebra travels forward with the resulting danger of pressure on the cauda equina. Adams has recently shown the relation of what might be termed unilateral spondylolisthesis to the production of scoliosis. It is apparent that changes in the position of the fifth lumbar vertebra are to be found quite frequently.

The two cases in my list were both men engaged in specially laborious work. One patient came up with a traumatic back strain which was perpetuated by an extremely faulty posture, of the round hollow back type. In neither case was the deformity a marked one. The old classical picture of spondylolisthesis as seen in the text books and in museum preparations must be rare, but the slighter forms which cannot be diagnosed on sight are probably quite common.

HYPERTROPHIC ARTHRITIS.

The seven examples of this condition all occurred in men above the age of forty-eight, who were following arduous occupations. In one only did the symptoms manifest themselves after a definite trauma. Six cases showed a lateral deviation of the trunk, three of the patients presenting the clinical symptoms of so-called sciatic scoliosis, with the list to the same side as the pain in two out of the three. There were no other noteworthy features in the group, the physical signs and radiographic appearances being of the usual type.

POSTURAL SACRO-ILIAC AND LUMBO-SACRAL STRAINS.

These groups present close inter-relationships; all three conditions may co-exist in the same patient, and it is not always possible to establish any definite boundary line between the several types.

1. *Postural Strain.* In four cases the chronic back ache was considered to be due entirely to the obviously extremely faulty body poise present. These individuals showed an absence of any signs which would definitely localize a lesion to the sacro-iliac or lumbo-sacral joints, and there were no abnormalities seen in the x-rays of these regions. No other physical condition was present, which might explain the pain in the back. All four patients had the type of bad posture associated with an increased lumbar lordosis and they were all curiously enough, Russian immigrants.

2. *Sacro-iliac Strains.* Under the generic title of sacro-iliac strain is grouped a most interesting class of cases. The term strain as applied to any joint is one which long usage has firmly established in clinical nomenclature but in itself it is not indicative of any one simple pathological lesion. It behooves us, therefore, to enquire closely into the exact lesion present in cases in this group.

In the present series of thirty-two lame backs, twelve examples of lesions of the sacro-iliac articulation designated as strain, are seen. It is extremely likely that in a much larger series the proportion would be considerably higher.

All twelve cases were under fifty years of age, and nine of them under forty-five. In five, the symptoms followed a very definite acute trauma. Seven cases showed a lateral deviation of the spine; four of them having unilateral sciatic pain with the list homologous in three.

It happens that in ten of these twelve cases the joint strain was right-sided; the two cases in which the left joint was the site of the trouble, both had had injuries unusual in this type of case; one man being run over by a motor car, whilst the other, a fat unwieldly individual of sedentary occupation, had fallen downstairs.

Whether this preponderance of right-sided lesion is a coincidence or not it is impossible to

say from such a small amount of material. In other joints, strains (using the term in a rude sense) may show such a predilection for one side. In the common internal derangement of the knee, viz: the displaced or torn internal semilunar cartilage, the left knee is affected in at least 70% of cases. This injury is seen in England largely in two classes of individuals, the foot baller and the coal miner. The frequency of involvement of the left knee has been explained by the fact that the majority of the twisting movements of the trunk occur from right to left, the left knee usually being firmly planted on the ground in the position of slight flexion. This may happen both on the football field and in the low seam in the mine, where the miner works in a cramped position.

Some such occupational asymmetry may perhaps explain the location of strains to the right sacro-iliac joint in men accustomed to very heavy lifting as in the present series of cases.

The skiagrams were singularly unproductive in this group of sacro-iliac strains; no abnormalities being seen either in the joints themselves or in the lumbo-sacral region.

There are three interesting and important facts about this group which I should like to emphasize. In the first place, no case showed gross displacement of the sacro-iliac joint demonstrable by x-ray; no case presented the physical signs of relaxation of the joints and no actual pathological process, such as for example, tuberculosis, was evident in any single one.

Gross displacements of the sacro-iliac joint can and do occur but they must necessarily be rare injuries; requiring a considerable degree of violence and showing signs of extreme crippling. This applies to both series.

Relaxation of the joints in the male, must also be uncommon. If for any reason the condition of strain becomes chronic and persistent, the joint changes are usually if not invariably in the nature of a progressive stiffening, rather than a relaxation. In the female, on the other hand, all the conditions, predisposing to relaxation of the pelvic joints are found. Such a change within limits, is physiological, occurring especially during pregnancy; the failure of normal involution of the joints in the puerperium, associated with the possible injury during labor, are factors which explain the likelihood of such relaxation being often seen in the female.

Many cases of sacro-iliac strain reported in the literature are classed loosely as joint relaxations, irrespective of sex. I think we must appreciate the sex difference in relation to these joints, both from an anatomical and a pathological standpoint. The male and the female joints may, of course, have lesions in common, but on the whole, the pathology of these joints differs widely on the two sexes: a difference which is based on inherent variations in function and structure. The anatomical side of the question has been worked out very thoroughly in the last few years by Derry.[5] The peculiar form of the human pelvis is a result of the assumption of the erect attitude. In the lower mammals the plane of the sacro-iliac joints is practically horizontal and the articular surface of the ilium is only in contact with the first and part of the second piece of the sacrum. The human pelvis has been dragged down posteriorly by the pull of the ham strings and glutei; the sacrum rotating on a transverse axis between the ilia, the whole pelvis rotating on the hips.

As a result of this the two components of the sacro-iliac articulation have been brought into a more intimate connection. In the male the rotation has proceeded to a greater degree than in the female. The female pelvis tends to preserve the more primitive form of the lower mammal; the sacrum is more horizontal, the plane of the brim forms a greater angle with the horizon and the auricular facet extends on to the second sacral segment. The sacral articular surface in the male has come into still greater relation with the ilium and it usually extends over the sacral segments and a part of the fourth. In addition the actual joint surfaces differ markedly in the two sexes.

The auricular facet of the ilium in the female forms a rounded condyloid area fitting into a correspondingly hollowed-out surface on the sacrum. The male auricular surfaces show irregular projections and ridges which fit in interlocking fashion into corresponding pits and grooves and the edge of the articular surface on its anterior aspect, is lipped so as to overlap the adjacent edge of the sacral facet.

The female sacro iliac joint as is well known is capable of considerable real motion and is a true diarthrosis. Derry has called it a condyloarthrosis, thus placing it in the same category as the wrist joint. Coincident with the capability of free motion and dependent directly on it there has developed in the female a very strong ligament in the antero inferior part of the capsule, a ligament which has produced the preauricular sulcus on the ilium, one of the distinguishing features of the female bone.

These characteristics of the female peivis and sacro-iliac joints are evidences of mechanical adaptation for the functions of labor. The male sacro-iliac joint is practically incapable of any motion. Its anatomical structure would suggest exceptional solidity and stability. Yet the undoubted frequency of strains in men engaged in the hardest kind of manual labor seems to point to some special vulnerability. In the class of patient as seen in the clinic of this hospital the sacro-iliac strain is the commonest of all joint strains.

It seems to me that the fixed, almost immovable nature of the male sacro-iliac joint, explains its weakness in withstanding the effects of strain.

Albee from a study of fifty joints in the dissecting room states that the sacro-iliac joint is always a true joint, that irrespective of age or

sex the variations are very slight and that the antero inferior part of the capsule is always very thin and weak, conclusions which are not in accord with the best anatomical investigations.

When we come to analyse the exact lesion underlying a sacro-iliac strain we are confounded with certain difficulties. The joint is not strictly comparable to a joint such as the knee or hip. The massive posterior sacro-iliac ligaments for the most part stand at some distance from the actual true joint capsule and it is, therefore, possible to have a strain or rupture of fibres of the ligaments without any direct injury to the capsule itself. We must thus recognize the possibility of two extreme types of strain; one type in which the lesion is limited to the more superficial bands of the various posterior sacro-iliac accessory ligaments, the other where there is a stretching or tearing of the joint capsule and some intra-articular injury, such as a laceration of the fibro cartilage and synovial membrane or even a fracture of one of the projecting hillocks of bone on the auricular facets. In the latter condition there will be the possibility of the occurrence of a slip of the interlocking surfaces. Such cases are met with; they show no abnormality in the radiogram and they may undergo spontaneous reduction, or may persist and require manipulation.

The relative frequency of these possible lesions all of which come under the heading of sacro-iliac strains, still require to be worked out in a large series of cases.

Certain clinical differences go with these several types of strain. Thus the presence of very marked muscle spasm in the back ham strings, and the extremes of the hip motions suggest a lesion involving the joint capsule and the joint interior.

The history of a sudden onset, with the feeling of a crick in the back, persistent acute nerve pain over the posterior aspect of the joint sometimes with sciatic pain and a marked muscular spasm, is indicative of a slip of the joint. In such cases the sciatic pain is true referred pain, the ripping of nerve endings due to the lesion, being referred along the distribution of nerve fibres derived from this same origin as the joint supply; actual mechanical irritation of the lumbo-sacral cord on the upper two trunks going to form the sacral plexus being an impossibility in a lesion of this kind.

In the present twelve cases only one gave a history suggesting a slight slip of the joint. The symptoms in this instance gradually disappeared with support and occasionally light manipulations without any anesthesia. A pure strain with no signs of a slip may present very acute symptoms with marked spasm and temporary crippling as was the case in one patient in this series who was seen eighteen hours after the onset.

The diagnostic features of sacro-iliac strain are familiar to most orthopedists but one point deserves further consideration and that is the question of the value of the straight leg-raising test. There has been a tendency to exaggerate the positive value of this test.

Unless there is a decided unilateral limitation of straight leg raising, the act causing pain in the back, localized accurately over the affected joint the test is of no confirmatory value. The statements "straight leg raising limited" or "straight leg raising test positive" which sometimes appear in reports of cases, are absolutely worthless. The considerable variations seen in normal persons in the degree to which this act is possible depend on the length of the hamstrings; not only do these muscles vary in individuals but may even vary on the two sides.

Lumbo-sacral Strain. Three cases fall into category. The oblique inclination of the plane of the lumbo-sacral joint apparently indicates potential instability, though the free motion and the presence of the thick cushion-like intervertebral disc are factors antagonistic to strain.

All three cases had chronic backache referred to the lumbo-sacral region, with the absence of any positive signs of sacro-iliac strain or arthritic changes in the lumbar spine. They do not present clear-cut types, the diagnosis being arrived at mostly by a process of exclusion.

Two cases showed a large transverse process on the fifth lumbar on the right side, with extreme likelihood of impingement on the ala of the sacrum. In addition both had a poor posture with lordosis. There was no pain in the lower extremities in any of the cases. The presence of this asymmetrical variation in the transverse processes did not sufficiently explain the symptoms and physical signs but may possibly be the primary factor in causing disturbances of function at the lumbo-sacral articulation, as in the cases described by Goldthwait.[7]

From these few ill-defined cases it is impossible to draw any conclusions of value.

There are many other cases of low back pain and in examining the type of case it is important to consider the possibility of lesions such as neoplasm of the lumbar spine and sacrum; inflammatory conditions and neoplasms of the spinal meninges, cord and cauda equina and pelvic visceral disease. If one constantly bears these in mind the chance of serious error is miminized.

I am indebted to Dr. E. G. Brackett for the privilege of studying the above series of cases in the Orthopedic Clinic of the Massachusetts General Hospital.

A STUDY OF THE VACCINE THERAPY OF TYPHOID FEVER.*

BY ALBERT A. HORNOR, M.D., BOSTON.

THIS article is based upon a study of 135 cases of typhoid fever, comparing 40 cases where vaccines were administered with 95 cases where vaccines were not used. The forty cases that received vaccines were those cases admitted to the First Medical Service of the Boston City Hospital between August 1 and October 15, 1913, excepting such cases as showed complications previous to entrance or had a normal temperature before the diagnosis was confirmed by a positive Widal reaction or blood culture. The ninety-five cases not receiving vaccines and used for comparison consist of those cases admitted to the two other medical services of the Boston City Hospital during the same period of time. The one hundred thirty-five cases were treated alike save for the use of vaccines.

The vaccine used in this work was made by suspending in physiological salt solution a twenty-four hour agar slant growth of bacillus typhosus and then killing the organisms by a thirty minute exposure to a temperature of 56° C. The culture of Bacillus Typhosus used is the same that is used at the Boston City Hospital for Widal reactions and for prophylactic inoculations.

The initial dose of the vaccine was ten million killed bacteria. The number of organisms injected was increased daily by ten million, being administered every afternoon for one week, then on alternate afternoons with a twenty million increase until the temperature remained normal for three days or patient had received seven hundred million dead bacilli. The average total number of organisms given each patient was five hundred and sixteen million. Furthermore, there is no difference between the average number of organisms administered to those patients who recovered without complications and to those patients who died or recovered in spite of complications.

The inoculations were intracuticular and were all accompanied by local reactions,—of redness, induration, pain and tenderness. These appeared within twenty-four hours and lasted twelve to forty-eight hours. No systemic reactions were detected.

The features of comparison, between those cases receiving vaccines and those cases not inoculated, studied in this work and tabulated below are: duration of fever in uncomplicated cases, incidence and character of complications, and mortality. The average duration of fever in uncomplicated cases treated with vaccines was 24.39 days; in uncomplicated cases not receiving vaccines was 23.08 days. The percentage of cases showing complications were: inoculated, 55; uninoculated, 50½; all cases, 51. The percentages of mortality were: of vaccinated cases, 10; of unvaccinated cases, 11½; of all cases, 11 1-10. (See Table No. 1.)

* Read at a meeting of the Boston Society of Medical Sciences, March 10, 1914.

TABLE NO. 1.

SHOWING MAIN FEATURES OF COMPARISON BETWEEN THOSE CASES TREATED WITH VACCINES AND THOSE TREATED WITHOUT VACCINES.

	All Cases. (135)	Vaccinated Cases. (40)	Unvaccinated Cases. (95)
Days fever lasted in uncomplicated cases	23.46	24.39	23.08
Percentage of cases showing complications	51	55	50.50
Mortality percentage	11.1	10	11.5

The duration of fever in uncomplicated cases was approximately the same whether the cases did or did not receive vaccines. Defervescence in the uncomplicated cases began usually on the third day after admission, no matter whether vaccines were or were not administered. A more detailed study of the incidence and of the character of complications shows relapses occurring in 20% of inoculated cases in contrast to 11.5% of uninoculated cases; recrudescences in 17.5% of inoculated cases as against 28.4% of uninoculated cases; other complications in 37.5% of inoculated cases compared with 21% of uninoculated cases. In brief, the incidence of recrudescence was much less in the vaccinated than in the unvaccinated cases, while relapses and other complications were much more frequent in those vaccinated than in those unvaccinated. The latter class of complications includes hemorrhage, perforation, phlebitis, pneumonia, parotitis, tonsillitis, osteomyelitis, acute hallucinosis, Vincent's angina, and decubitus. (See Table No. 2.)

TABLE NO. 2.

SHOWING INCIDENCE AND CHARACTER OF COMPLICATIONS IN PERCENTAGE.

	All Cases. (135)	Vaccinated Cases. (40)	Unvaccinated Cases. (95)
All complications	51	55	50
Relapse	14.7	20	11.5
Recrudescence	25.1	17.5	28.4
Hemorrhage	3.74	7.5	2.15
Phlebitis	1.48	5	0
Perforation	1.48	2.5	1.05
Pneumonia	6.66	10.25	4.15
Parotitis	0.74	2.5	0
Tonsillitis	3.74	2.5	4.15
Cholangitis	1.48	2.5	1.05
Decubitus	2.22	5	1.05
Furunculosis	2.22	2.5	2.15
Osteomyelitis	0.74	2.5	0
Vincent's angina	0.74	2.5	0
Miscarriage	0.74	0	1.05
Acute hallucinosis	0.74	0	1.05

Analyzing the causes of the four deaths occurring among cases treated with vaccines, we find the first death due to an intestinal perforation, after the fifth inoculation of vaccine and after patient had received a total of 150 million dead bacilli; the second death was due to septic parotitis developing during a relapse which began after three weeks without fever and after patient had received 880 million killed bacteria; the third death was due to an intestinal hemorrhage occurring on eighteenth day after patient's admission to the hospital and after he had received 530 million dead organisms; the fourth death was due to bronchopneumonia on patient's twenty-first day in hospital and after he had received 580 million killed typhoid bacilli. These deaths were obviously not due to complications extraneous to typhoid fever.

The deaths occurring among the 95 cases not inoculated with dead typhoid bacilli were as follows: 4 pneumonia, 2 hemorrhage, 3 severity of the disease, 1 perforation, 1 alcoholism.

The more important articles which suggested this work were as follows: First that by Callison, pathologist to the Manhattan Eye, Ear and Throat Hospital in *American Journal Medical Sciences* for September, 1913, wherein he reports 475 cases of typhoid fever treated with vaccines by various men and showing a mortality of 6.5% and a 6.5% incidence of relapse. Second, the work of Captain Smallman of the English Army Medical Corps, who reports 36 cases of typhoid fever treated with vaccines, having a mortality of 8.3%. Third, the report of 41 cases by Meakins of the Royal Victoria Hospital, Montreal, where he used from 1000 to 4500 million killed bacteria—polyvalent non-autogenous vaccine,—with the death-rate of 4.6% and incidence of relapse of 2.3% among cases so treated, contrasted with a death-rate of 12.2% and an incidence of relapse of 13% among cases not vaccinated.

In the endeavor to be conservative and mindful of the absence of any good theoretical basis for the use of vaccines in cases of septicemia, the dosage used in this series was small, but frequently repeated.

The value of this work is entirely negative. Using the kind of vaccine and the doses already outlined, we find, first, no obvious systemic reaction to the vaccines; second, a local reaction to every inoculation with dead organisms, and third, no diminution of the duration of fever in uncomplicated cases nor of the incidence of complications, nor of mortality.

RINDERPEST IN THE PHILIPPINES.—Report from Manila, P. I., on June 15 states that the rinderpest or cattle-plague is rapidly spreading in the islands. Means are being taken to prevent its further extension.

THE FUNCTION OF THE SOCIAL SERVICE OF THE PSYCHOPATHIC HOSPITAL, BOSTON.*

BY MARY C. JARRETT, BOSTON,

Chief of the Social Service, Psychopathic Department, Boston State Hospital.

THE Psychopathic Hospital in Boston is the embodiment of an ideal long upheld by the Massachusetts State Board of Insanity and definitely expressed in their annual report as early as 1902. There a plan was sketched for a hospital with an out-patient department, to be conducted along the lines of a general hospital "for the study and treatment of patients" and "for scientific research"; to receive the insane who cannot be cared for at home "pending the legal formalities" preliminary to commitment to an insane hospital, and patients in the "incipient stages of mental disorder, who might never have to enter an insane hospital if they could obtain temporary relief from unusual stress, or be removed from unfavorable environment, or have the advice and supervision which might be afforded through the out-patient department of a hospital." Two years ago this hospital was opened in Boston in close relation with the main hospital for the insane of the Metropolitan District, the Boston State Hospital, and under the supervision of the same board of trustees.

The psychopathic hospital idea began to be put into practice abroad over thirty years ago, and there are now in Europe over 50 institutions for specialized care and investigation of the insane. In the United States there are psychopathic hospitals in four states,—in Michigan the Psychopathic Ward of the Hospital of the University of Michigan at Ann Arbor, in New York the Psychiatric Institute of the New York Lunacy Commission and Pavilion F of the Albany General Hospital, in Massachusetts the Boston Psychopathic Hospital, and in Maryland the Phipps Institute just opened as a part of the Johns Hopkins Hospital.

The patients at the Psychopathic Hospital in Boston either come voluntarily, or are received at the request of a physician, or are sent by the court or the police. The probate court may commit a person for thirty or sixty days' observation on the application of two physicians, the criminal court may commit a person under arrest pending a hearing, and the police may bring directly to the hospital an acutely insane person who comes under their care. The capacity of the hospital is 110 beds, and the average number of admissions is 125 a month. The cases include insanity, mental deficiency, psychoneurosis, alcoholism, and the types of mental and moral defect associated with delinquency

* Psychopathic Hospital Contribution 1914.5. The previous contribution 1914.4 by Dr. E. E. Southard, entitled "Feeble-mindedness as a Leading Social Problem," was published in the BOSTON MEDICAL AND SURGICAL JOURNAL, Vol. clxx, No. 00, 1914, p. 000.

for which methods of diagnosis and classification have not yet been discovered.

The problems presented by the patients coming to the out-patient department may be grouped as follows: The question of insanity, the question of feeble-mindedness, psychoneurosis, alcoholism, speech defect, and delinquency, possibly the result of mental abnormality. About 30% of the 700 patients admitted to the out-patient department between August, 1912, and June, 1913, came through a general knowledge of the hospital, and as a rule we had no information about such patients except what they told us; 18% came through hospitals, physicians or other interested persons, usually with only a brief note or a card of introduction; 24% were discharged patients from our own wards; 28% came from schools, courts, or social agencies which had more or less information and gave us a written history of the patient.

The direct demand upon the hospital social service is lessened about 25% by the fact that a large number of our cases are already in the care of the social agencies which refer them, and that these agencies not only undertake to secure the histories of the patients, but make themselves responsible for their care and treatment according to advice from the hospital; but there are many points at which the social workers of the hospital can facilitate the efforts of these agencies.

The need of social service in some form can safely be assumed in the case of every insane, mentally deficient or neurasthenic patient who comes to the hospital, but we have estimated that the need is considerably less pressing or less readily discovered in about 30% of our cases. These include some of the chronic insane who are committed to insane hospitals, persons of confirmed bad habits who have no fixed residence, with whom communication could probably not be maintained, and patients who have in their own families somebody who takes the social worker's place.

Nearly one-half of the cases, then, both house patients and out-patients, should come at once directly under the social service. The different types of social service for which these cases indicate a need can best be illustrated by brief descriptions of patients who have been admitted to the hospital or examined in the out-patient department. Some cases require a different form of social treatment from others; often several forms are required in the same case. The main groups under which the work of the social service would seem to fall are: (1) After-care or supervision of patients at home, (2) advice to families of patients in regard to their care, (3) prophylaxis for other members of the family, (4) relief, (5) reference to a social agency or an institution, (6) inquiry to secure a history that is needed for the doctors' diagnosis, (7) inquiry to learn whether conditions can be secured suitable for the discharge of the patient.

These types may be illustrated as follows:—

1. Cases showing the need of after-care or supervision:—

CASE 1. John C—, 36 years old, engineer. Married at 21 and lived ten years with his wife, took a dislike to her and separated. Four years ago began to be annoyed by spirits. Delusions that the devil has got his soul. Hallucinated. Discharged after six weeks, improved. Diagnosis: Paranoid dementia praecox. His conduct had been good, and he was advised to go out to work again.

Problem: The patient should have been advised as to suitable employment and a proper place to live. If he had difficulty in finding them for himself, he should have been assisted. He should be visited to see whether his delusions return and whether he is capable of self-support.

CASE 2. Ethel B—, 23 years old, waitress. Sent from a general hospital where she had been with pneumonia. Had hallucinations and required restraint. Unable to walk. Father dead, mother in court for stealing. Discharged much improved, capable of self-support. Diagnosis: Alcoholic polyneuritis. To report to out-patient department and has not done so.

Problem: A good boarding place should have been found and employment under good conditions, and friends who could strengthen the patient's resolution to abstain from alcohol.

CASE 3. Eva A—, 33 years old, widow, one son. Sent to out-patient department by the court after arrest for drunkenness. Claimed she tripped on the street after drinking small amount of beer; that she rarely drinks enough to become drunk; has lived as housemaid in a minister's family. A brother is in an asylum as the result of drinking. Examination did not indicate chronic alcoholism. Her case was dismissed in court. She was advised to report in a month to the out-patient department.

Problem: The patient should be constantly in touch with someone who will make her realize her danger in continuing to drink. She should be helped to settle in new surroundings where the temptation will be less.

CASE 4. Amos R—, 26 years old, meat packer, single. Always of peculiar temperament; pious, liked to be alone, silent, a good workman. Two weeks before admission refused to talk, to move or feed himself. Diagnosis: Dementia praecox (catatonic episode). Remained two weeks and for the last ten days was in good physical and mental condition. Considered recovered. In two months was brought in by the police, apathetic and rambling. Was committed to an insane hospital.

Problem: The patient should have been under observation so that the return of his symptoms might have been detected at the earliest possible time, when he should have been brought to the out-patient department. His home conditions should have been looked into and changed if unfavorable to his recovery.

Case 5. Grace B—, 28 years old. Married, three children. Has been a bookkeeper. In Psychopathic Hospital with diagnosis of alcoholic hallucinosis for five weeks; returned in less than a month and stayed two months; readmitted after six months and remained seven weeks. Each time discharged recovered. Has lately lived apart from her husband who is a degenerate and toward whom she feels contempt and hatred. Is fond of her children who are staying with relatives. Her mother was in an insane hospital several years with manic-depressive insanity. Patient is weak, impulsive, pleasure-loving. Before her last admission she made a determined effort to hold a position in a hospital but under discouragement and worry she again succumbed.

Problem: After the first discharge employment should have been found for the patient, and she should have been advised where to make her home. She has no one in her family upon whom she can rely, and she is easily discouraged.

Case 6. Simon G—, 12 years old. Lives with his mother and father and one brother. Admitted to the hospital from out-patient department for observation. Father had syphilis. Boy is continually giving trouble. At four years stole money and hid it in the ground. Somewhat later held burning matches against the faces of younger children, and laughed at the burns. Several times chopped off door knobs with a hatchet; has thrown marbles through neighbors' windows; attempted to set fire to the barn; frequently loses a new article of clothing and shows no concern, though the family is not well-to-do; destroyed the gas meter. Mother can tell twenty or thirty incidents of his maliciously destroying things about the house. Lies about his acts, when there have been witnesses. Masturbates. Incites other boys to mischief and watches the results gleefully.

Problem: The family should have been induced to bring the boy to the hospital for treatment for syphilis, and advised about his training. His mental development should be closely watched, and he should be studied with the object of determining whether he is mentally defective.

Case 7. Edna B—, 19 years old. Living with married sister. Has had bad dreams and on waking loses power of walking until she can recall the dreams. Hears her grandmother, for whom she has a dislike, telling her to stick needles and pins into herself, has stuck many needles and pins into her breast. Admitted to hospital and discharged improved. Diagnosis: Hysteria. Continued to come to out-patient department, had recurrence of attack. Again recovered and went to work, getting back into her natural social life. Later reports she is well and working in a store, but cannot sleep.

Problem: Employment should be found that is not too exacting and is under good hygienic conditions. It should be arranged that the patient lead a regular life with the proper amount of recreation of the right character.

Case 8. Mildred D—, 14 years. Living with parents, brothers and sisters. Bright, capable, well-behaved child, rather sensitive nature. Has lately begun to have hysterical convulsions. Has been admitted to the hospital twice.

Father is a hard drinker and is violent and abusive when drunk. He preceded the family to this country and when the patient with her mother joined him four years ago, it was a great shock to her to find him a drinking man. She has come to have a terror of him when he is intoxicated. At other times he is kind. The mother is a very nice woman and all the children are of the same good character as patient. Patient has been working in a factory, although she wished to continue school, because the family needed her wages.

Problem: The father's drinking habits should be inquired into, and an effort made to cause him to improve. If this is not possible arrangements should be made for the patient to live away from home until she is stronger. It should be arranged with the family that she go to the trade school instead of returning to work.

Group II. Cases showing the need of advice to the patient's family:—

Case 1. Nora C—, 47 years old, married. On admission markedly depressed, apparently very weak, complained of many indefinite pains. At times feels that she cannot breathe if she does not swallow first. No hallucinations. After three days her sister, who was anxious for her to come to the hospital, insisted on taking her out. Provisional diagnosis: Neurasthenia.

Problem: The family's prejudice against the hospital should have been overcome so that the patient could have stayed until sufficiently recovered.

Case 2. James K—, 60 years old. Married 29 years ago, has seven children at home, oldest 22 and youngest 9, all boys except two girls, 18 and 14, and has a married daughter in New York. Patient's story: His wife was never kind to him but he bore with her for the children's sake, feeling that he would have them to depend upon in his old age. But with the exception of the girls, they have sided with his wife and treat him with disrespect and unkindness. His wife nags him continually and neglects his needs; has put him out of the house winter nights when he has slept on a bench in the park. When he comes home tired from work and goes to bed, his wife says he is drunk. He is a cabinet maker; has been in charge of six workmen and earned $24 a week, working five years at a time for at least two firms, but now that he is old cannot get as good positions as formerly. He sent his three oldest children through high school, and has had some of them given music lessons. Before he came to the hospital he turned on the gas to kill himself, feeling that he had nothing to live for. When he leaves he will not live again with his wife and will have nothing to do with his sons; but will work and give all the money he can spare to his two unmarried daughters.

Wife's story: Patient has always been a hard drinker, for the last two years has seldom been

sober. Has several times threatened the life of his wife and children and lately attempted suicide.

On admission had delusions that people were trying to choke him at night. Stayed a month and was discharged recovered. Diagnosis: Alcoholic hallucinosis. A month later returned, hearing voices and can not sleep. In two weeks mind again entirely clear.

Problem: It should be learned whether it is true that the patient's wife is harsh and nags him and his children are indifferent to him. If this is exaggeration he should be made to see the facts. His wife and children should be made to understand that kind treatment is essential and their coöperation should be gained to prevent further attacks.

CASE 3. John V—, 14 years old. Lives with parents and two younger brothers. Sent by the principal of the grammar school with the question to what extent he is responsible for his disorderly conduct. Out of 42 school reports of conduct only 2 were "good," 12 "fair," 28 "poor" or "very poor." His misconduct was said to be of a thoughtless kind but he was always in trouble. His father brought him to the out-patient department where he had a preliminary mental examination; but failed to bring him again and did not respond to a letter asking him to return for the completion of the examination.

Problem: The father and mother should have been seen and had explained to them the importance of discovering early whether mental defect may be an element in the boy's conduct.

Group III. Cases showing the need of prophylaxis for other members of patient's family.

CASE 1. Julius R—, 33 years old, widower, mechanic. One child, a boy of 15. Niece of 12 lives with them. The father, a brother and a sister are in insane hospitals in this state, and an aunt has been in an insane hospital. Since wife's death over four years ago, has gone on a spree every three months for a few days. Brought in by the police who found him in his back yard with a club looking for the people who had wired his house for a dictagraph to kill them. After a month in the hospital, had cleared up and showed no evidence of psychosis. Was discharged to the out-patient department on visit. Diagnosis: Alcoholic hallucinosis.

Problem: When there is such a history of insanity in the family, the patient's son and niece ought to be examined to see whether they show any mental abnormality. Other members of the family ought also to be looked up.

CASE 2. Walter A—, 17 years old. Living with parents and one sister 19, the only living child. Four died in infancy after premature birth, and there were two miscarriages. Sister had chorea a year ago. Father's mother and one sister died of "paralysis" and one of his brothers is "eccentric." Patient works in a provision store where his father is in charge but could not hold a job elsewhere. Stolid, indifferent, obedient, kind and well behaved. Sent to out-patient department by family doctor. Diagnosis: Congenital syphilis. Admitted to hospital for salvarsan treatment. Failed to report a month later as directed. Sister was not examined.

Problem: The history of "nervousness" in the patient's sister makes it important that she should be under observation. From the family history it is probable that some of the cousins should also be examined.

CASE 3. Ernest W—. Receiving treatment for tabo-paresis. Twelve years old. Lives with mother who is separated from father. One other child, a girl of 14, shows marked nervousness and a commencing process of tabes. Mother at doctor's suggestion brought her for examination, but failed to bring her for treatment.

Problem. The mother should be informed of the importance of treatment for the girl and should be persuaded to have it given, in the hope of arresting the disease.

Group IV. Cases showing need of relief:—

CASE 1. Miriam I—, 34 years old, married. Husband and two children, younger two years. Two years ago in very hot weather had a week when she imagined people were telling her what to do, crawled about the floor and tried to wash the black off the walls. Completely recovered according to husband. For three months previous to admission had been developing delusions and hallucinations of persecution. Brought in excited and irrelevant and became maniacal. After two months committed to an insane hospital unimproved.

Problem: How are the children being cared for? The father, an ignorant man, needs advice in making suitable provisions for two small children. The mother after her admission was not at any time rational enough to discuss the matter.

CASE 2. Rebecca E—, 6 years old. Father a tailor. Seven other children in family, oldest 16 years. Boy of 16 is described by mother as nervous and backward, and the baby, one year old, twitches. The first child, who died, was feeble-minded. Father can not earn more than $12 a week and has lost time through being sick. The family has had some public relief. Physically normal, markedly nervous. By mental tests child appears to be subnormal but it is not clear that she is mentally deficient.

Problem: The mother, seen at the clinic, is anxious and strained with the effort to keep the children fed and clothed, and cannot give this child the special care she should have. Sufficient income should be secured for the family, and all the children should be kept under observation.

Group V. Showing the need of reference to a social agency or an institution:—

CASE 1. Francis D—, 12 years old. Living with parents, father a bridge caretaker. Five other children from 18 to 7 years in the family. Brought by

school teacher because he is so nervous that he cannot attend school. Underdeveloped, undernourished boy. By Binet tests measures 9 years. Question is how much of his mental backwardness is due to his physicial condition? Advised summer in the country under good conditions.

Problem: The doctor's prescription could not be filled by the family, for they had no relatives or friends to whom they could send the boy for the summer. A children's agency should have been asked to give him special care in a boarding home.

CASE 2. Bertha B—, 25 years old. Bright looking, rather attractive. Has illegitimate child six years old in care of a charitable agency. During the past four years five social agencies had been interested in her; two physicians had examined her, one of whom had recommended commitment to a school for the feeble-minded two years before. Sent for examination by a college professor in whose family patient had worked who thought this physician's diagnosis was unjust to her. Examination showed her to be distinctly subnormal, probably a high-grade moron. Her social history was not secured until later and no action was taken. When the history was obtained it confirmed the diagnosis of feeble-mindedness. Meanwhile she was heard of staying with some friends, changing positions frequently, and keeping company with a married man. Finally she married a man who is considered "peculiar."

Problem: Efforts should have been made to secure the patient's commitment to a school for the feeble-minded. Now that she is married, she will probably never be committed, but will bear other children who may be feeble-minded.

Group VI. Cases showing the need of a history required for diagnosis.

CASE 1. Henry R—, 54 years old, storekeeper, married. Two grown sons and two grown daughters. Committed by the Probate Court on the statement of two physicians that he had violent outburst and homicidal tendencies and had carried weapons. The patient was orderly and tractable, at first unwilling to tell his whole story, finally gave the following history: His trouble is due to his wife's partiality for a lawyer with whom she has intimate relations, which he suspects to be immoral. This man posted her on points of law and she got control of part of her husband's business. She was successful and he was not; she domineered over him making him of no account in the family and denying him his natural rights. Their children joined with her against him. His sons have beaten him on several occasions. An unscrupulous doctor is conspiring with the family to have him committed to an institution. His wife has often threatened during the past year to have him adjudged insane and sent away.

The wife's story is that her husband always had a very bad temper which has lately grown worse. The present trouble is all because she took the lease of a lodging house in her name as she is a better manager than he and she found he was wasting the receipts from tenants. He has been grossly immoral. She has been true to him, but he is suspicious and jealous. He goes among the neighbors slandering her and her daughters.

Some inquiry by a member of the staff brought out the fact that the patient and his wife had for a long time kept an immoral house in the West End. Inquiry was not pursued and patient was discharged without diagnosis.

Problem: Are the patient's beliefs about his wife the delusions of a paranoid condition or are they facts? Can his wife's story be believed? The facts can be learned only by inquiry among people who know the family. Without these facts the patient's mental condition cannot be determined.

CASE 2. James R—, 37 years old, telegrapher. Married and has three boys 12, 10 and 3. Committed by the court for observation because he became excited in the court room.

Patient said that he was here because of family trouble and told the following story: A year after his marriage, 15 years ago, his wife's sister began to interfere in his domestic affairs. His wife is an angel outside but a devil at home and she and her sister want to get rid of him. His wife told him she had been unfaithful to him and he went away to New Hampshire. Came home on hearing that his wife was about to have him arrested for non-support. Continued to have trouble and was arrested this week for failure to provide in spite of the fact that he offered his wife money. In court he became greatly excited because everybody believed her and nobody believed him, and was sent to the hospital. He had been once before in an insane hospital where no definite psychosis was found. At that time he had attacked his wife when drunk. Patient gave no evidence of a psychosis while here and though it was believed that he might be insane, not enough evidence was found for commitment and he was discharged. He got a job on a boat, went home after a short cruise, and his wife immediately had him committed again to the psychopathic hospital, saying that he had threatened to kill her and the children and had broken the furniture. He says this is not true and his wife wants to get him out of the way. His condition is unchanged.

Problem: As the stories of the patient and his wife are contradictory, it is necessary to learn from others what their domestic relations have been, and whether there have been witnesses to his alleged outbursts.

CASE 3. Julia E—, 43 years old, married. No children. Married a year ago, separated after a month. Admitted relation since with a married man. Five years ago was for several weeks in a sanatarium and under court supervision for two years. Now committed by the court. On admission apprehensive and depressed. No hallucinations. Believed conscience was punishing her dreadfully for specific offences of sex nature of which she told. No delusions of any other nature. Discharged after three weeks by order of court to custody of her husband. Diagnosis not made.

Problem: Inquiry among relatives and friends was needed to secure information about

the temperament of the patient and her conduct and habits, in order to judge the importance of the symptoms she showed in the hospital. For lack of information she had to be discharged without a diagnosis.

CASE 4. Alice B—, 67 years old, widow. Sent for seven-days' observation by physician, who was called in after quarrel between her and sister with whom she lives, on statements of sister. Fifteen months ago she came to live with her sister whose husband had died leaving some money. Sister says now she does not think patient is insane, but patient thinks sister is insane and refuses to return to her. Is willing to remain as voluntary patient. Sister's lawyer's wife says sister has been insane for 30 years. Patient in the hospital shows no evidence of mental disease.

Problem: Inquiry should be made about the patient and her sister to learn whether either have given evidence of mental disorder in the past.

Group VII. Cases showing need of investigation to determine whether patient may properly be discharged:—

CASE 1. Julia K—, 20 years old, vestmaker. Parents dead. Lived with grandmother and two brothers. Brought by police because she had been excited for two days, tried to choke her grandmother and destroyed furniture. Diagnosis: Dementia precox (catatonia). Improved a gread deal and at the urgent request of a doctor was discharged in his care on visit. In two months shot herself; recovered from wound and was readmitted to Psychopathic Hospital. Transferred after four months to Boston State Hospital, improved.

Problem: The fitness of the family doctor to be responsible for the patient should have been investigated before her discharge and the living conditions to which she was to return should have been looked up. Then the hospital should have kept in touch with him and with the patient, so that she might have been brought back at the earliest signs of another attack.

CASE 2. Laura E—, 37 years old. Married 11 years, has two children, boy 10 and girl 6. Symptoms: Headache, numbness, palpitations, fear that she was going to die. Believed her husband unfaithful, had been abusive to her and she hated him. Told of sexual experiences of which she had been the victim since two years old. Discharged improved after two months. Diagnosis: Neurasthenia. In nine months returned in a maniacal condition and was committed to an insane hospital.

Problem: Inquiry should have been made to discover whether conditions in the patient's home were such that her improvement could be expected to continue. The grounds of her antipathy to her husband should have been discovered. If investigation showed that she ought not to return to him, she should have been helped to make arrangements to live elsewhere.

CASE 3. John A—, 21 years old. Single. Newsboy. According to his family left the house in the morning apparently normal. Brought in by the police. Had a knife with which he intended to kill a supposed enemy. Patient said he had heard voices for three years; knew two people who had been influencing him and giving him cramps. After two weeks claimed that he had been mistaken in his delusions and denied that he had them any longer. Discharged on visit at the request of a lawyer who agreed to see that he was taken care of. Diagnosis: Dementia praecox.

Problem: The lawyer's ability to assume responsibility for the patient should have been investigated and the plans for his care should have been known to be suitable. The patient is potentially dangerous, and the hospital should have kept in touch with him so that he might be brought back if his delusions returned.

What are the conclusions as to the function of social service in a psychopathic hospital? Is there a need for members of the staff whose whole duty is concerned with the patient in his social relations? Unquestionably there is much to be done outside the hospital in the care of the insane; and much of the information necessary to an understanding of mental disease cannot be obtained in the hospital. An estimate based on a study of 100 cases in the hospital and 100 cases in the out-patient department indicates that the cases needing social service from the hospital will fall into the groups illustrated above as follows: About 50% will require aftercare or supervision, 35% advice to the patient's family, 25% a history for diagnosis, 15% investigation to show whether the patient may properly be discharged, 5% prophylaxis for other members of the family, 5% relief, 5% reference to a social agency. Some cases will require more than one form of social service. It is not possible for the medical staff to cover this work. The doctor whose time is already filled with examination and treatment of patients and clinical research work has not the time to follow the patients beyond the doors of the hospital, or to make any systematic effort to obtain the facts of their past lives and present environment beyond what can be learned from relatives or friends who visit the hospital.

Complete and thorough histories are needed for scientific research in the correlation of social disorders and mental disorders. Since environment is so evidently a factor in producing mental disease and mental disease is so evidently a factor in producing social disorder, it would seem of great importance that the relation between mental abnormality and social conduct should be scientifically studied, and determined effort made to secure the case material for such study. It cannot be expected that the medical staff should devote a part of their time to collecting and studying this material. If a hospital acknowledges this object, an adequately organized social service staff is a necessary part of its equipment.

Without the social service, "the study and treatment of patients" in the Psychopathic Hospital in at least the majority of cases, must remain incomplete, and "scientific study" must be limited to purely medical subjects. So in order to carry out the aim of the hospital, held in view by the State Board of Insanity, since 1902, the social service has been planned as an integral part of the work. The beginning is being made with two visitors, who will carry only the proportion of cases that it is found they can cover adequately, and the expectation is that by the addition of other visitors, all the cases will be eventually covered.

Medical Progress.

PROGRESS IN PEDIATRICS. THE PHYSIOLOGY OF DIGESTION AND THE METABOLISM IN INFANCY. A SUMMARY.

By John Lovett Morse, A.M., M.D., Boston.

THE CALORIC NEEDS OF INFANTS.

It has been found by metabolism experiments and by the continuous observation of nursing infants that the average infant needs between 100 and 120 calories per kilogram of body weight during the first six months in order to gain properly in weight. After the first six months the organism works more economically and a smaller number of calories are sufficient, 75 to 100 calories per kilogram being enough for the average baby. Young babies will usually hold their weight on from 70 to 75 calories per kilogram, but cannot gain on this amount. Premature babies, on account of their larger surface area in proportion to their bulk, need rather more calories per kilogram of weight than do full-term babies. A certain number of babies need more than 120 calories per kilogram in order to thrive, some babies requiring as much as 140 or 150 calories.

It is far more rational to calculate the caloric needs in relation to the surface area of the baby than in relation to the weight. There are various formulae for determining the surface area which are approximately accurate. There are no figures, however, from large series of cases as to the average caloric needs of babies calculated on this basis. The figures as to the average caloric needs of babies have been determined, moreover, without relation to whether the babies were quiet or active. It has recently been discovered, however, that the active baby uses up many more calories than does the quiet baby and that, therefore, the caloric needs must vary with the activity of the individual baby as well as with its size.

THE METABOLISM OF FAT.

Fat is a very important source of energy to the infant because of its high caloric value. The large proportion of fat in human milk indicates how large a proportion of the total energy required may be advantageously provided by fat. The tolerance for cows' milk fat varies within wide limits. If an intolerance for fat is once established, it persists longer than that due to any of the other food elements. It is difficult to make up for a marked deficiency in fat by an increase in the carbohydrates in the food. Fat and carbohydrates do not serve, moreover, exactly the same purpose, the metabolic water formed from fat being much greater than that formed from the carbohydrates.

Effect on Gastric Motility. Nothing has so much influence on the time required for the emptying of the stomach as variations in the amount of fat in the food, the time required varying directly with the amount of fat. Raising the percentage of fat in the food, for example, from three per cent. to six per cent., more than doubles the time occupied in emptying the stomach. An excess of fat in the food may so retard the emptying of the stomach that stagnation of the gastric contents occurs. When the quantity of the fat is very large, selective retention of the fat takes place. Fat delays the secretion of hydrochloric acid and hence delays the establishment of the pyloric reflex. The delay in the secretion of hydrochloric acid interferes also with the closure of the cardiac sphincter. The food may, therefore, be pushed back into the esophagus by the peristaltic action of the stomach and regurgitation result.

Digestion of Fat. There is unquestionably a gastric fat-splitting ferment present at birth, which is active during infancy. There is some doubt as to how important this action is. In all probability it plays but a small part in the total amount of fat-splitting, which is chiefly accomplished in the intestine. The processes in the intestine are the same as in the adult. Not more than one percent. of the fat escapes splitting under normal conditions. Nature prevents, moreover, a very active participation of the gastric lipase in the splitting of the fat, because, when the casein is coagulated, the fat is entangled in its meshes. The casein has to be digested, therefore, before the fat can be reached by the digestive juices. This takes place slowly. Only a small amount of fat can be acted upon, therefore, at one time.

Absorption of Fat. Under normal conditions, fat absorption is extraordinarily good in health. Under normal conditions more than 91 percent. is absorbed, in some instances as much as 98 percent. The fat absorption is practically the same on cow's milk as on human milk. From eight percent. to 11 percent of the ingested fat is absorbed in the upper part of the small intestine, the absorption being nearly complete at the ileocecal valve. Under ordinary conditions

there is very little absorption in the large intestine, but under certain favorable conditions the large intestine is capable of absorbing large amounts of fat. There is much difference of opinion as to the form in which fats are absorbed, whether as fatty acids or soaps and, if as soaps, whether as the soluble soaps or the insoluble soaps. It is safe to say that at present this question is not settled.

Fat in the Stools. Practically all of the fecal fat comes from the food, not from the intestinal secretions. During the first few days of life as much as 50 percent. of the dried stools consists of fat. This amount may diminish to as little as 15 percent. as the babies grow older, although in some instances from 25 percent. to 40 percent. of the dried stool of the normal infant consists of fat. About ten percent of this fat is in the form of neutral fat, ten percent. in the form of soluble soaps and the rest in the form of fatty acids and insoluble soaps.

Results of an Excess of Fat. When there is an excess of fat in the food, and this fat passes from the stomach into the intestine, it combines there with alkalis, chiefly the earthy, to form the so-called "soap stools." The organism is, therefore, deprived of magnesium and calcium. More magnesium and calcium are lost, however, than can be accounted for by the binding power of the fatty acids. There is not as much interference with the absorption of fat under these circumstances, nevertheless, as would be expected. These stools are only found when there is not only an excess of fat but also a lack of carbohydrate in the intestine, conditions under which putrefaction of protein can take place. After the stools become acid, the fat is present in the form of soft, fatty curds. There is then no longer a loss of magnesium and calcium, but of potassium and sodium.

When there is an excess of the lower fatty acids in the intestines they may produce diarrhea. In these cases there is a great loss of fat in the stools. The fat under these circumstances is combined with the alkaline salts, especially sodium, not with the alkaline earths. A relative acidosis results, with an excess of ammonia in the urine. Even when there is a severe diarrhea, the calcium and magnesium may be well retained.

In normal babies in whom the fat absorption is normal, an increase in the intake of fat has no influence on the mineral composition of the feces. In conditions of chronic malnutrition, an increase in the fat in the food causes a considerable increase in the salt output through the feces. In such conditions the loss of mineral bases may be sufficient to cause a negative salt balance.

THE METABOLISM OF CARBOHYDRATES.

The carbohydrates comprise the sugars and starches. They are not tissue builders, but serve simply as sources of energy. The caloric value of the sugars and starches is the same. They make the digestion of protein more complete, however, and have a marked property of sparing nitrogen. When they are added to the food there is usually an increase in the nitrogen retention. When given in excess, on the other hand, they cause increased peristalsis, frequent stools and a considerable loss of nitrogen from the body.

The carbohydrates begin to leave the stomach almost immediately after they are ingested and pass into the intestine more quickly than the other food elements. They also hasten the passage of protein from the stomach into the duodenum.

SUGARS: *The Chemistry of Sugars.* Three different sugars are commonly used in the feeding of infants. These are lactose, or milk sugar, saccharose, or cane sugar, and maltose, or malt sugar. Maltose is never used in the pure form, because of its cost. The sugars which are ordinarily spoken of as malt sugars are in reality combinations of maltose and the various dextrins. These sugars are all dissacharides, lactose being a combination of dextrose and galactose, saccharose of dextrose and levulose, and maltose of dextrose and dextrose. The dextrins are bodies which are formed in the change from starch to maltose. There are a great variety of them and their exact composition is not well known. The dextrins being finally converted to maltose, their ultimate end is dextrose.

Absorption of Sugars. The dissacharides are not absorbed as such from the intestine under normal conditions, but are first broken down into their respective monosaccharides by special ferments. These ferments are maltase, saccharase (invertin) and lactase. They are formed in the mucous membrane of the small intestine and are all present and active at birth. Maltase is also present in the blood, the saliva and the pancreatic juice. The greater part of the digestion and absorption of the carbohydrates takes place in the upper part of the small intestine, but splitting and absorption may also take place in the large intestine.

The monosaccharides which are formed are taken up by the portal capillaries and carried by the portal vein to the liver where they are converted into and stored as glycogen, to be later reconverted by the maltase in the blood into dextrose and used as required. There is normally about one-tenth percent. of dextrose in the blood. A deficit of sugar in the blood is made up from the glycogen deposits. If hyperglycemia occurs as the result of some disturbance of the regulatory apparatus, the excess is eliminated in the urine. The carbohydrates are ultimately broken down into carbon dioxide and water. The various intermediary products which are formed during their disintegration in the body are, however, entirely unknown.

Energy Value of Sugars. The gross energy value of the various disaccharides is the same.

The net energy value of maltose may be, however, greater than that of the others in certain conditions of malnutrition in which the store of glycogen in the liver is depleted or exhausted. Dextrose after being absorbed can be immediately utilized, if necessary, without being previously converted into glycogen. The whole of the energy value of maltose, which is composed of dextrose and dextrose, is thus immediately available, while only one-half of that of the other disaccharides, which are only one-half dextrose, is available at once, the galactose and levulose having to be converted into glycogen before they can be used. Under normal conditions, in which the monosaccharides are all changed to glycogen before being utilized, this difference in energy value does not hold.

Assimilation of Sugars. When milk sugar is injected directly into the circulation it can be completely recovered in the urine. When cane sugar is introduced subcutaneously into animals, 65 percent. or more is excreted in the urine. The remainder is eliminated into the alimentary tract through the gastric mucosa, the salivary glands and the bile. Milk sugar and cane sugar are passed out of the system in this way because there are no ferments in the blood capable of converting these sugars. When maltose is injected it can be broken down by the maltase in the blood and retained.

If an excessive amount of disaccharide is introduced into the intestine, or there is a lesion of the intestinal wall, it will pass into the circulation before it is broken down into the monosaccharides. When the disaccharides reach the circulation in this way, their fate is the same as when they are injected directly into the circulation. All the lactose and the major part of the saccharose are eliminated unchanged in the urine, the rest of the saccharose being eliminated through the alimentary tract, where it may be broken down and partly or entirely utilized. The maltose, unless greatly in excess, is broken down and retained. The limits of assimilation of single doses of disaccharides in infancy are: lactose, 3.1 to 3.6 grams per kilogramme; saccharose, no data, but probably about the same as lactose; maltose, 7.7 grams per kilogramme. These limits are much higher than the amounts of sugar which a baby would receive in a single feeding of breast milk, or in a single feeding of any reasonable artificial food.

Sugar-Fever. It has been believed by many that sugar may cause fever. Leopold found that 43 percent. of the babies tested with lactose, 42 percent. of those with saccharose and 33 percent of those with maltose reacted with fever. This fever was, however, always accompanied by diarrhea, and in none of the cases tested in which the stools remained normal did the sugar cause fever. The recent experiments of Schlutz make it appear very improbable, moreover, that, even when there are lesions of the intestine, the rise of temperature is caused directly by the sugar.

Fermentation of Sugars and the Results. The disaccharides are all fermentable. Lactose undergoes lactic acid fermentation more readily than the other sugars. Saccharose undergoes alcoholic fermentation most easily, and butyric acid next most readily, while maltose is especially prone to butyric fermentation and next to alcoholic.

The maintenance of the normal infantile intestinal flora depends on the presence of a relative excess of carbohydrates in the food, the fermentation of which keeps the reaction of the intestinal contents acid. Lactose is broken down less rapidly and is consequently more slowly absorbed than the other sugars. It is, therefore, better fitted than the other disaccharides to maintain an acid reaction throughout the whole intestinal tract. Few organisms other than those normal to the intestinal tract of infants can, moreover, utilize lactose before it is broken down, while many can utilize saccharose and maltose.

Certain organisms, such as the dysentery bacillus, form toxic substances from protein and innocuous substances from carbohydrates. These organisms always grow by preference on carbohydrates instead of protein, if both are present. Other organisms thrive on protein, but grow with difficulty on carbohydrates. The administration of an easily fermentable carbohydrate will change the activity of many organisms from the proteolytic to the fermentative type and will favor the growth of fermentative organisms which will crowd out the purely proteolytic forms. All the disaccharides are easily fermentable. Milk sugar is preferable to the others because, being more slowly broken down, its action is more prolonged.

The excessive fermentation of sugar may produce an unduly acid reaction of the intestinal contents and cause diarrhea and injury of the intestinal mucosa. When given in excess, lactose causes diarrhea more often than the other disaccharides, presumably because it is more slowly broken down and therefore stays in the intestines longer. The opportunity for the production of an excessive acidity and for injury to the intestinal wall is consequently greater. Under such conditions the sugars which are more quickly broken down and absorbed are more suitable.

STARCH: *Amylolytic Ferments.* Amylolytic ferments are present in the saliva and pancreatic secretion of the new-born infant, even if it is born prematurely. These ferments are present and active in the breast-fed as well as in the artificially-fed infant. The amylase of the pancreatic secretion is more abundant after the first month than before. The activity of the pancreatic amylase seems to depend, after the first month, more on individual peculiarities than on the age of the baby. The amount of the secretion is apparently independent of the character of the food. It is not diminished in atrophic conditions.

Digestion and Absorption of Starch. During the process of digestion, starch passes through the various forms of the dextrins and is finally converted into maltose. The maltose is then broken down into dextrose and dextrose before it is absorbed. The digestion of the starch is carried on in the stomach by the salivary amylase until its action is stopped by the hydrochloric acid in the gastric secretion. It is completed in the intestine by the action of the pancreatic amylase. The part played by the salivary amylase is, however, relatively unimportant.

Owing to the facts that starch is slowly broken down and that the maltose which is formed is quickly absorbed in the form of dextrose, there is only a relatively small amount of fermentable carbohydrates present in the intestine at any one time. Starch can be utilized, therefore, without causing disturbance in certain conditions in which the disaccharides cause fermentation.

Barley and oat starch are broken down more rapidly by enzymes and bacteria than are wheat and rye starch and are, therefore, more likely to cause acidity and fermentation. The fermentation of starches results in the formation of free fatty acids which exert a strong irritant action on the intestine. The injurious effect of these acids is the same whether they are derived from carbohydrates or fat.

Starch a Protective Colloid. Starch acts as a protective colloid. It thus prevents the formation of large casein curds and makes the digestion of casein easier.

A baby on a purely carbohydrate diet, or on one in which the carbohydrates are greatly in excess, receives much less salts than it should, such a diet being poor in salts. The consequent disturbance in the retention of salts and water results in impairment of the nutrition and a marked diminution in the resistance to infection.

THE METABOLISM OF PROTEIN.

Rennin, pepsin, hydrochloric acid, trypsin and erepsin are present and active at birth, even if this occurs prematurely. The infant is, therefore, fully prepared to digest protein as soon as it is born.

Pepsin, in the presence of hydrochloric acid, reduces the protein to albumoses and peptones. The trypsin of the pancreatic juice and the erepsin of the small intestine split these products into polypeptides and finally into amino-acids. The amino-acids are the end products of protein digestion. They are absorbed and reconstructed in the body into various substances, which are at present not completely understood. They are excreted by the kidneys, chiefly in the form of urea and ammonia.

The nitrogenous constituents of the food are almost entirely broken down and absorbed. The nitrogen of the feces is derived almost entirely from the intestinal secretions and from bacteria.

Protein, which is the only food element which contains nitrogen, is absolutely essential not only for the growth and development of the baby but also for its survival, since the body tissues can only be replaced and new tissues formed from the nitrogenous foods. A baby can readily die, although taking a food containing a sufficient number of calories, if its protein content is consistently below the minimum protein need. This minimum protein need lies between 1.5 grams and 2 grams per kilogram of body weight. The infant requires protein not only to replace wasted tissues, as does the adult, but also to build up new tissues. The demand for protein is, therefore, relatively greater than that of the adult. The eagerness of the infant to retain nitrogen is surprising. Growth seems to be as necessary a process for it as is the maintenance of the nitrogenous equlibrium for the adult. The baby will retain protein, if it is in any way possible. In the adult a diet of insufficient caloric value leads to protein loss. This is not the case in the infant. Instead of utilizing all the food ingested to furnish energy, the infant continues to use nitrogen for growth and sacrifices other tissues of the body. It retains a considerable amount of nitrogen even when the caloric value of the food is insufficient. That is, an infant will often grow in length while losing weight. It grows at the expense of its general nutrition. The infant can also use protein to furnish heat and energy. The caloric value of protein is the same as that of the carbohydrates. 28.6% of the caloric value is, however, given off as free heat, leaving only 71.4% available for the purposes of cell life. Protein is, therefore, not an economical form of fuel. The excretion of the products of the combustion of protein throw, moreover, an unnecessary load on the organs of elimination. Under normal conditions in infancy, especially when the food is human milk, protein plays but a small part as a source of energy.

Judging from the constant composition of breast-milk, the amount of protein required does not need to be much increased after the first few months until the end of the first year. The rate of growth diminishes as the wear and tear of the body increases and the two factors approximately balance each other. If an infant is temporarily deprived of nitrogen and then given it freely, it retains a large amount for a time. If an excess continues to be given, only the normal amount is retained Nitrogen retention is especially high during the convalescence from atrophic conditions.

The sparing of nitrogen and the storing of nitrogen are materially modified by the composition of the food as a whole. Fat does not spare protein, as might be expected from its high caloric value, but carbohydrates have a marked influence on the retention of nitrogen. The mineral salts must have a very decided influence on the storage of nitrogen, because the retention of nitrogen and of salts run parallel

with each other. The explanation of this fact is that salts are necessary for the building up of living protein material. Nitrogen cannot be retained unless they are available and is, therefore, excreted.

According to Orgler's experiments, healthy artificially-fed infants retain nitrogen as well or better than healthy breast-fed infants of the same age. Sick artificially-fed infants retain it as well as sick breast-fed infants. Healthy infants when given a properly modified cows' milk often retain nitrogen better than when on the breast. The utilization of nitrogen may be as good or even better in the artificially-fed than in the breast-fed.

It is evident, therefore, that the casein of cows' milk is not as difficult of digestion as has been supposed in the past. It may, however, appear in the stools in the form of large, hard curds. The loss of nitrogen in this way is, nevertheless, relatively slight and they are often present without any other signs of disturbance of the digestion.

No injurious effects have been proven to be caused by the presence of larger amounts of protein in the food than are ordinarily present in human milk. Holt and Levene have produced fever in infants by feeding foods containing a large amount of "synthetic" protein. They concluded that the fever was directly due to the action of the absorbed protein, and that the reason that it caused fever was because the food contained a large amount of protein without a sufficient amount of whey. Their food contained a large amount of salts, however, and it is possible that the fever may have been due to them. It is possible, too, that, in general, an excess of protein may increase heat production and thus cause an excessive stimulation of the metabolism of all the foodstuffs.

THE METABOLISM OF THE SALTS.

The salts are necessary for the maintenance of life. They are best absorbed and utilized when they are in organic combination with foodstuffs. The ash content of the newly-born infant is 2.7% of the total weight; that of the adult, 4.4%. About 4% of the mineral intake is retained in the early months and later only about 2%. Human milk contains about 0.2% of ash and cows' milk about 0.7%. The relations of the various mineral constituents to each other are materially different in the two milks. The salts are, moreover, not in the same organic combinations in the two milks. The special combination of the salts in the whey of human milk is more favorable to the absorption and retention of both the fat and casein of both human and cows' milk than that in the whey of cows' milk.

The ash intake in the artificially-fed is from six to nine times that in the breast-fed. The absorption of ash is from 15% to 25% better on human milk, but, on account of the larger intake, from four to six times as much is absorbed in artificial feeding. The greater percentage of absorption on human milk depends especially on the better absorption of calcium, magnesium and phosphorus. The retention of the salts of human milk is better than in the case of cows' milk. About one-third of the salts are eliminated through the feces and two-thirds through the urine when human milk is taken, while on cows' milk about one-half is eliminated in each.

There are marked changes in the metabolism of the salts as a whole in the disturbances of nutrition. In the milder conditions there is a slight decrease in retention of the salts, especially of the alkaline earths. In the more severe disturbances there is a very material loss, especially of the fixed alkalis. Calcium and magnesium are used up by the fatty acids in the stools, while, when there is diarrhea, sodium and potassium are lost. A condition of relative acidosis develops as the result. In the severest cases the nature of the disturbance of the salt metabolism is but little known, but is presumably a very serious one.

Calcium. There is almost always a sufficient amount of calcium in the food whether it is human milk or cows' milk. There is much more calcium in cows' than in human milk and the amount absorbed and retained is greater, although the percentage of retention is less. Only five per cent. to ten per cent. of the calcium ingested is eliminated in the urine, the remainder passing out in the feces, calcium being absorbed and then excreted into the large intestine. Calcium forms a much greater part of the artificially-fed than of the breast-fed infant's feces. It is largely in the form of the insoluble soaps. There is an abnormal elimination of calcium in the feces in rickets. There is also a diminution in the retention of calcium in the spasmophilic diathesis.

Iron. Both human and cows' milk are deficient in iron, and anemia would always develop in infants after a few months, if it were not for the store of iron present in the liver at birth. Iron is almost entirely eliminated through the feces.

Magnesium. The metabolic functions of magnesium and calcium are very much the same. The distribution of magnesium in the tissues is a little wider than that of calcium. Magnesium also makes up a considerable proportion of the total ash of bone. The absorption of magnesium takes place through the small intestine and is relatively high. It varies with the amount of fat in the food, less being absorbed when the food is high in fat. Magnesium is excreted in about equal amounts through the urine and feces.

Phosphorus. Cows' milk contains about five times as much phosphorus as human milk. 77% of the phosphorus of mothers' milk is in organic combination, however, while only 27.9% of the phosphorus in cows' milk is combined in this way. This relation of the organic to the in-

organic phosphorus is of importance, because the organism does not have the power of building cells containing phosphorus from the inorganic phosphates. The absorption of phosphorus on human milk is higher than on cows' milk. The amount of absorption increases with the amount of fat in the food. The presence of a large amount of calcium in the food results in the formation of insoluble salts of phosphorus on the intestine and thus prevents absorption. The organism retains phosphorus longer than any other mineral constituent except sodium chloride, presumably because of its close connection with the central nervous system. Phosphorus is eliminated in about equal amounts through the urine and feces, except when there is a large excess of calcium in the food, when it is eliminated through the feces. The retention of phosphorus is disturbed in rickets. It has a close connection with the intermediary metabolism, it being necessary to the proper functioning of the thyroid gland, the ovaries and the testes.

Sodium and Potassium. There is much more sodium and potassium in cows' milk than in human milk. There is more potassium than sodium in both of them. The absorption of these salts is good for both milks. The retention is better on human milk than on cows' milk, being 67% for sodium and 74% for potassium on human milk, while on cows' milk it is 15.27% for sodium and 16.12% for potassium. Both salts are eliminated in the urine and feces, 15% to 25% of the intake being eliminated in the feces. In disturbances of metabolism the fixed alkalis are retained as long as possible. An over-retention of potassium almost never occurs. It is probable that a retention of sodium chloride precedes water retention in edema. It is probable that an excess of sodium chloride may cause a rise in temperature. This occurs more easily in babies with disturbances of nutrition than under normal conditions.

Sulphur. There is about ten times as much sulphur in cows' milk as in human milk. Ninety per cent. or more is absorbed from both. Absorption takes place through the small intestine. The retention of sulphur is much better when human milk is taken than when cows' milk is taken. Sulphur is eliminated almost entirely in the urine, but a small part is eliminated into the large intestine. The retention of sulphur is somewhat diminished in rickets.

The various salts, with the exception of iron, are present in sufficient quantities and in the proper proportions in human milk. In most modifications of cows' milk there is an excess of salts. This excess is usually unimportant in the feeding of normal infants, but may play an important part when there are disturbances of the nutrition. Little is known as to the conditions in which the salt content of the food should be changed or to what degree each or all of the constituents should be varied.

Book Reviews.

The Sensory and Motor Disorders of the Heart. Their Nature and Treatment. By ALEXANDER MORISON, M.D., F.R.C.P. New York: William Wood and Company.

Morison has written a very interesting book of some two hundred and fifty pages. The fact that the style is somewhat controversial detracts little from the interest or the value of the book. Morison allies himself strongly with the neurogenists. While some of the book is obviously special pleading, yet the author has a strong array of facts to support his case. The first part, on the nature of cardiac action, is based considerably on his own researches and is the best part of the book. There can be little doubt of Dr. Morison's extensive clinical experience, but the clinical part is not as succinctly stated as the parts dealing with pathological anatomy and pathological physiology.

Modern Surgery, General and Operative. By JOHN CHALMERS DACOSTA, M.D., LL.D.; Samuel D. Gross professor of surgery, Jefferson Medical College, Philadelphia; surgeon to the Jefferson Medical College Hospital; surgeon to St. Joseph's Hospital, Philadelphia; fellow of the American Surgical Association; member of the American Philosophical Society; Membre de la Societé International de Chirurgie; Member of the Medical Reserve Corps, U. S. Navy, etc. Seventh edition, revised, enlarged, and reset. With 1085 illustrations, some of them in colors. Philadelphia and London: W. B. Saunders Company. 1914.

DaCosta's "Modern Surgery" was originally written in 1894. Every single year since that time, with the exception of 1897, it has been either revised, reset, reprinted, or recopyrighted. Further testimony as to its popularity is unnecessary. The book is now a volume of more than 1500 pages and is, in reality, a small encyclopedia. The type is good and sharp. The paper is pleasant to the eye. The pictures are simple and very satisfactory. Throughout, it is interesting and accurate. Perhaps the most interesting page of the entire volume is the preface, in which the author's style and personality is best exemplified. In the reviewer's judgment, DaCosta's work is the best single volume text-book upon general and operative surgery which has been produced in English. It may be unhesitatingly recommended to all medical students.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JUNE 25, 1914.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States. $6.56 per year for all foreign countries belonging to the Postal Union.*

Papers for publication, and all other communications for the Editorial Department, should be sent to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston. All orders for reprints must be sent in writing to the Editor on or before the day of publication.

The Journal will furnish 100 reprints free, if requested in writing.

All letters containing business communications, or referring to the publication, subscription or advertising department of the Journal, should be addressed to the undersigned.

Remittances should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

HOUSE SCREENING AS A SANITARY MEASURE.

IN the rural districts, the question of screening against insect pests assumes greater importance than in the towns and cities. This is because the house fly and the mosquito find in the country the ideal conditions for breeding. Theoretically the manure piles and the pools of stagnant water could be eradicated from the countryside as readily as from the streets of the cities, but practically a lack of money for sanitary improvements and the more or less sparsely settled population make this highly specialized sanitation which obtains in the cities impossible. Consequently in order to preserve health and comfort it is necessary to resort to the protection afforded by measures intended to keep the insect pests out of the dwellings. On first thought it would seem that such a simple question as screening windows and doors was hardly within the province of the physician. However a little consideration will serve to show that in reality this is a problem in preventive medicine well worthy the careful attention of the country doctor. In order to be a safeguard at all screening must be effective. Half-way measures are of little avail. One of the neglected matters in this problem is the time at which screens are first put up. In the early spring a few flies appear and no attention is paid to them. About ten days later these flies commence to lay their first batch of eggs and then in another ten days the first large swarm of flies make their appearance. Then the people commence to put up the screens, which should have been up two or three weeks earlier.

This screening, undertaken at a date which is entirely too late, is apt to be hurriedly done and to be deficient in many ways. Few people realize the ease with which flies and mosquitoes can find the loopholes in the barrier erected against them. One of the chief of these consists in small holes which have rusted through the mesh of a cheap screen left over from the previous summer. Another is the space left between the door and the jamb, which results from the warping of the light framework. One of the most important of the openings is that which is found in the space between the sliding sashes of adjustable window screens, which are meant to slip in under the raised window and rest between it and the sill. Screens of this kind are almost never efficient. These mistakes in screening commonly arise from a mistaken conception of what constitutes true economy in the matter of screening material and framework. In the first place the frames should be solid and be made to last a lifetime for both doors and windows. Properly made frames can be refitted with wire mesh as often as required and should be a part of the specifications in every newly built house. When it comes to a consideration of the mesh, there is room for the indulgence of considerable leeway in the amount of money to be expended. A wire mesh that is fine enough to keep out every sort of bug and insect will also keep out too much air. As the mesh occurs in the market in four degrees of fineness, one can ascertain for himself which will more easily answer his purpose, and be influenced accordingly. However, it must be said that the ordinary mesh with twelve strands of wire to the inch is too coarse to keep out mosquitoes, and can only be made safe by so many coats of paint that the air is thereby largely excluded. The larger the mesh the coarser the wire, and consequently the longer the life of the screen, therefore one must try to find the coarsest wire and largest mesh which will exclude the insects which are a menace in his community. No. 14 wire mesh with one coat of paint will keep out the house fly effectually and it will also keep out the malarial bearing mosquitoes. This sized mesh can be bought almost anywhere in the United States at considerably less than $2.00 per 100 square feet. In the seaport towns where the Stegomyia calopus exists, a finer mesh must be used. In the sanitation of the Isthmian

Canal Zone, No. 18 was the one which was found the most effective. Whatever the size of the mesh desired the life of the screen can be lengthened by a coat of paint. But in this connection it must be remembered that small meshes readily stop up by paint, consequently it is better to get a size a little too large and reduce it by painting.

But even though the house be thus scientifically screened, the work will be ineffectual unless the details of springs on the doors and stopping of fireplaces be carefully attended to. Mosquitoes do not as a rule fly very high, but they will at times pass over houses, and when attracted by the open chimneys will often enter the house in this way. Keyholes are also another favorite way of entry. In fact, any small holes of any kind will attract the mosquito. Once having made his entry into the house by means of small holes the mosquito does not readily find his way out again, and hence a badly screened house, instead of becoming free from the pest, becomes a veritable mosquito trap, in which hundreds of the insects are imprisoned, and which is more dangerous to its human inmates than if it were not screened at all. There are many more details of screening which are well worth the careful attention of the physician who cares to make himself an authority on the prevention of disease, as well as its cure, but those we have mentioned should be sufficient to stimulate interest in this badly neglected subject.

MEDICAL LEGISLATION. REORGANIZATION OF THE STATE BOARD OF HEALTH.

IN the issue of the JOURNAL for May 21 (Vol. clxx, pp. 817-819) we printed in full the text of the proposed "act to create a state department of health and to amend the public health laws," with the Governor's special message on May 12 transmitting it to the legislature. In the same issue, and in other numbers of the JOURNAL, we have from time to time commented editorially on this bill (House No. 2598) and on the reorganization of the state board of health, which it involves.

Meantime, this bill has been under consideration by the House committee on ways and means, to which it was referred, and which, with two dissenting members, has finally voted to report it favorably, but with several amendments. The more important of these changes have been summarized as follows:—

"The provision in section 3 that the public health council created by the act shall meet at least once in each month, and at such other times as they shall determine by their rules 'or upon the request of any two members' is changed to read 'or four members and upon the request of the commissioner of health.'

"In the same section (section 3) the provision that the rules and regulations promulgated by the public health council shall have the force and effect of law remains, but the penalty is stricken out."

The first amendment seems good, the second rather unfortunate, since it merely invites disobedience of the rules by taking away the sting that makes their violation inconvenient.

"Section 4 originally provided for six divisions in the state department of health—namely, administration, communicable diseases, sanitary engineering, food and drugs, laboratories and child welfare, together with such other divisions as the commissioner of health may from time to time determine. The re-draft provides that there shall be such divisions as the commissioner may, with the approval of the governor and council, from time to time determine.

"The provision in section 5 of the original bill prescribing eleven specific duties which each district health officer shall, under the direction of the commissioner, perform, is simplified by providing that he shall perform such duties as may be prescribed by the commissioner, shall act as the commissioner's representative and, under his direction, secure the enforcement of health rules and regulations.

"Section 6, which originally gave to the public health council the right to decide that local health authorities were failing or refusing to enforce the laws and regulations to prevent the spread of contagious or infectious diseases, is changed in the redraft so as to vest that power in the commissioner's hands."

The first two of these amendments are in the interest of simplification; the third wisely aims to increase the power and authority of the health commissioner.

"A new section provides that present employees shall be continued in office until their successors shall be appointed and qualified or until removed by the commissioner.

"The bill carries an appropriation of $16,000 over and above the amount already appropriated for the state board of health for 1914. Some further minor changes may be made."

None of these changes importantly modifies the general purpose of the measure, but all are

concerned with matters of detail. It is earnestly to be hoped that the bill as amended may be passed by the present legislature, rather than that needful action on this important subject should be postponed to another legislative season.

On June 18 the redraft of this bill (now known as House No. 2742) was ordered by the House to a third reading on a rising vote of 102 to 27.

DANGERS IN THE USE OF ANTIMENINGOCOCCIC SERUM.

The old time death-rate from epidemic cerebrospinal meningitis was, in round numbers, 80%. Now it is 20%. This is solely due to the timely use of the antimeningococcic serum perfected by Flexner. All observers are unanimous in their opinion that this serum is effectual; and with the perfection in the methods of diagnosis by spinal puncture and microscopical examination of the withdrawn fluid, it is becoming more and more uncommon for cases of this disease to have progressed so far that the use of the serum does not effect a prompt cure.

However, it seems likely that the greater part of the 20% mortality is due to the fact that the diagnosis in these fatal cases has for one reason or another been delayed until after the third or fourth day of the disease. That some of this mortality is due to other causes cannot be denied. Chief among these are, first, an overwhelming infection and, second, disastrous effects due to the serum itself. The first of these causes is beyond our control. The second is more amenable to careful supervision.

From a study made by Hale (Hygienic Laboratory Bulletin No. 91) it was found that the possibility of death from the serum was twofold. The first of these was death due to increased intracranial tension from the injection of the serum itself. The second was due to the poisonous effects of the preservative tricresol, which is added to the serum. The symptoms of a dangerous increase of intracranial tension are an enormous rise in blood-pressure preceding a sudden fall and embarrassment of the respiratory centers. This increase in blood-pressure may rise to twice its former height. The practical danger from this source is, however, very slight indeed, as shown by Hale, experimenting with dogs and cats, who was able to produce death in this way in only a few instances out of a large number of attempts. With the usual precautions of injecting the required amount of serum slowly after a still larger amount of spinal fluid has been withdrawn, it would seem that an accident of this kind would be well nigh impossible. When we come to consider the effects of the tricresol, the question assumes a different aspect. Hale's experiments showed conclusively that this preservative was capable of causing death from respiratory failure. But there are certain danger signals which, if closely observed, will usually give ample warning of the impending catastrophe. As in the case of respiratory embarrassment from increased intracranial tension, the index of danger is to be found in the state of the blood-pressure. But, contrary to that condition, the change in blood-pressure consists in a steady fall. When the fall has reached a total of 20 m.m. in an adult having a normal pressure of 110 to 120 m.m. the danger point is approaching, and to avoid fatal poisoning of the respiratory centers by tricresol, the injection should at once be stopped.

The fact that the tricresol preservative carries with it a potential danger increases the responsibility of the physician administering the serum and makes it highly desirable that some more harmless preservative may be found. Experiments recently undertaken at the Rockefeller Institute by Auer* seem to indicate that some volatile antiseptic may be used with less danger than tricresol. He found that when 0.3 per cent. ether was added to the serum there was decidely less fall in blood-pressure and less respiratory embarrassment than when the tricresol was used. It appears that one of the chief advantages of using a volatile preservative, like ether or chloroform, consists in the fact that the preservative may be largely expelled from the serum by the simple expedient of heating the container just before its administration. Although Auer admits the danger from the tricresol preservative, it is plain to be seen that he considers it is one that is slight and easily to be combated. His experiments served to show that dogs are much more susceptible to the deleterious influence than are monkeys. As men and monkeys are much alike in their re-

* John Auer, B.S., M.D.: Journal American Medical Association, June 6, 1914.

actions to intraspinal injections, it would seem that Auer's experiments rather offset the dangers which are so apparent in the experiments of Hale on dogs and cats. At any rate the actually proven value of the serum is so great that its use should not be abandoned on account of the potential dangers of the preservative usually employed in its manufacture. This is especially true when the potential danger needs but to be understood in order to be largely prevented.

MEDICAL NOTES.

HONORARY DEGREES FOR PHYSICIANS.—At the recent commencement of Yale University the honorary degree of LL.D. was conferred on Dr. William Crawford Gorgas, surgeon-general of the United States Army; that of D.Sc., on Dr. Richard Pearson Strong, professor of tropical medicine in the Harvard Medical School; and that of A.M. on Dr. Fred Towsley Murphy, professor of surgery in Washington University, St. Louis; on Dr. John Howland, professor of pediatrics at Johns Hopkins University; on Dr. Henry Hun, professor of nervous diseases in the Albany Medical College; on Dr. Elliott Proctor Joslin, of Boston; on Dr. Edward Robinson Baldwin of Saranac Lake; and on Dr. Oliver Cotton Smith, of Hartford, Conn.

At the recent commencement of Brown University, the honorary degree of LL.D., was conferred on Dr. Charles William Eliot, president emeritus of Harvard; and that of D.Sc., on Dr. L. Emmett Holt, of New York.

At the recent commencement of Harvard University, the honorary degree of A.M. was conferred on Dr. Milton J. Rosenau, of Boston, who was described by President Lowell on this occasion as "Milton Joseph Rosenau, professor of preventive medicine in the Harvard Medical School; a physician whose aim is not to cure disease but to preserve health, and whose only patient is all mankind."

AMERICAN ASSOCIATION OF IMMUNOLOGISTS.—The first annual meeting of the American Association of Immunologists was held on Monday of this week, June 22, at Atlantic City, N. J. Among the papers presented may be mentioned one by Dr. J. Whitridge Williams of Baltimore, on "Abderhalden's Pregnancy Test." The discussion of Dr. Frederic E. Sondern's paper on "The Influence of Vaccine Therapy on Blood Morphology" was opened by Dr. George P. Sanborn, of Boston. In the evening the presidential address was delivered by Dr. Gerald B. Webb, of Colorado Springs, Colo. The secretary of the association is Dr. Martin J. Synnott, of Montclair, N. J.

MUNIFICENT ENDOWMENT FOR MEDICAL EDUCATION.—The will of the late James Campbell of St. Louis provides that upon the death of his widow and daughter his entire estate, estimated at $35,000,000, shall revert to St. Louis University, "for the erection, equipment and maintenance of a hospital in St. Louis county for sick and injured persons and for the advancement of the sciences of medicine and surgery absolutely and forever." It is believed that this is the largest single gift ever made to any medical or educational institution.

MAINE MEDICAL ASSOCIATION.—The annual meeting of the Maine Medical Association was held at Portland on June 10 and 11. Papers were read by Dr. John Sturgis of Auburn, Dr. C. M. Robinson, Dr. C. H. Hunt and Dr. J. A. Spaulding, of Portland; Dr. B. L. Wright of Portsmouth, surgeon in the United States navy; Dr. Richard F. Chase of Boston; and Dr. C. W. Pillsbury of Saco.

BOSTON AND NEW ENGLAND.

LONG ISLAND HOSPITAL TRAINING SCHOOL.—The annual graduation exercises of the Long Island Hospital training school were held at the hospital on Saturday of last week, June 13. The principal address was made by Governor Walsh, who presented diplomas to a class of 13 graduating nurses.

NOTIFICATION OF PELLAGRA AND RABIES.—At its meeting on May 7, the Massachusetts state board of health voted to add pellagra, rabies, and German measles to the list of notifiable diseases, and declared pellagra and rabies diseases dangerous to the public health.

SMALLPOX IN BROCKTON.—Two cases of smallpox were reported last week at Brockton, Mass., both in unvaccinated non-residents of the city.

Harvard Dental Alumni Association.—The forty-third annual meeting of the Harvard Dental Alumni Association, held in Boston on June 15, was attended by about 500 members. Dr. Charles A. Jameson presided, and the principal address was delivered by Dr. E. H. Smith. The following officers were elected for the ensuing year: President, Dr. Harold DeW. Cross; secretary, Dr. Frank T. Taylor; treasurer, Dr. Charles T. Warner; executive committee, Dr. Leroy M. S. Miner; trustees for life membership fund, Dr. Horace L. Howe; committee on nomination and election, Dr. Walter A. Bradford, Dr. Maurice E. Peters and Dr. Charles E. Stevens. Dr. George A. Sullivan, of South Boston, has been appointed one of the three United States delegates to the International Dental Congress to be held at London in August, 1914.

Harvard Medical Alumni Association.—The annual meeting of the Harvard Medical Alumni Association was held in Harvard Hall at Cambridge, Mass., on Commencement Day, Thursday, June 18. After the meeting the usual spread was served in Thayer Hall. Dr. Arthur Brewster Emmons, 2nd, was elected secretary of the Association for a term of three years, and the following were elected members of the council: Dr. John B. Blake, of Boston, for three years, and Drs. Horace Binney and Channing Frothingham, Jr., of Boston, and Dr. Silas A. Houghton, of Brookline, for four years.

NEW YORK.

Abolition of Positions, Board of Ambulance Service.—At a meeting of the Board of Ambulance Service, held on June 10, a resolution was passed abolishing the positions of director, deputy director, and registrar. The action of the board is in line with the policy recently outlined by Charities Commissioner Kingsbury, and recommended by the Hospital Investigating Committee, to consolidate the various hospital boards. None of the offices abolished were held by physicians.

Interstate Park.—The new Interstate Park, which has been rendered possible by private munificence and state appropriations, will make 18,000 acres of natural woodland accessible to the people of New York and New Jersey, and will include a river driveway of unequalled scenery from Fort Lee, opposite New York City, to Newburgh, sixty miles up the Hudson. On June 11 the Bear Mountain tract, in the Highlands, a few miles below West Point, was visited by an inspection party, among which were Governor Glynn, Mayor Mitchel, and other public officials, and on June 14 this portion of the park was formally opened to the public. Camping privileges, boating on a beautiful lake, the "Bloody Pond" of Revolutionary fame, and other facilities for outdoor life and enjoyment are offered free of charge, and transportation by steamboat, meals, refreshments, etc., at minimum prices.

An Unsuspected Case of Smallpox.—The chief of the bureau of infectious diseases received something of a shock the other day, when a man who came to the offices of the bureau at the health department to ask for a certificate of health was found to be actually suffering from smallpox.

Bequests.—By the will of the late Dr. Everett Herrick of New York more than $140,000 is left to institutions and charitable societies. Among the bequests are $50,000 to the American Academy of Medicine,—$25,000 to establish an "Everett Herrick Library Fund," and $25,000 to establish an "Everett Herrick" General Fund"; $25,000 each to the New York Skin and Cancer Hospital and the Free Library at Easthampton, Long Island; and $10,000 each to the Society for the Relief of Widows and Orphans of Medical Men and the Association for Improving the Condition of the Poor.

By the will of the late Harris C. Fahnestock, president of the First National Bank, New York, $100,000 each is left to the Presbyterian and St. Luke's Hospitals, the New York Post-Graduate Medical School and Hospital, the Charity Organization Society, and the Association for Improving the Condition of the Poor.

Yale Medical School.—It is announced that the Yale Medical School, which hopes to form an alliance with the New Haven General Hospital, has received from the Brady family, of New York and Albany, a gift of $125,000 for the erection and equipment of a clinical and pathological laboratory, the building to be known as the Anthony N. Brady Memorial Laboratory. The family has also pledged $500,000

to establish an Anthony N. Brady Memorial Foundation in the medical school, on condition that Yale University in ten years obtains a total of $2,000,000 for medical school endowment and building funds, exclusive of gifts from the Brady family.

MILK AT OTISVILLE SANATORIUM.—In connection with its tuberculosis sanatorium at Otisville the City Health Department maintains a model dairy in which the cattle are all high-grade, tuberculin-tested Holsteins. With the establishment of a bacteriological laboratory at the sanatorium, arrangements have now been completed for regular weekly examinations of the milk supplied to the patients. The first bacterial count showed that the milk from the dairy contained less than 10,000 bacteria per c.c.

SPREAD OF TUBERCULOSIS.—In order to determine, as far as possible, the ultimate disposition of applicants refused admission to tuberculosis sanatoriums, and thereby to arrive at an approximate estimate of any bearing such cases may have upon the spread of tuberculosis, the following data concerning 165 rejected applicants who sought admission to the Otisville Sanatorium have been collected: Of the 165 patients, 66 had negative sputum and may practically be disregarded. A majority of these either did not show any clinical evidences of tuberculosis or were suffering from some other disease which overshadowed an insignificant tuberculous lesion. The remaining 99 all had positive sputum and were too far advanced to be admitted, although at Otisville more advanced cases are accepted than is usual at other sanatoriums. All of these were urged to obtain hospital treatment, but only 62 entered hospitals; 37 remained at large,—known active distributors of tubercle bacilli, and only 9 of these could be induced to attend day camps, where a moderate degree of control could be exercised. Nothing but an increase in the infirmary capacity of sanatoriums, the health department states, will provide for and protect the community from cases of this class.

MORTALITY FOR WEEK ENDING JUNE 13, 1914.—There were 1365 deaths and a death-rate of 12.75 per 1000 of the population reported during the past week, as against 1303 deaths and a rate of 12.65 during the corresponding week of 1913, an absolute increase of 62 deaths and of .10 of a point in the rate, which is equivalent to a relative increase of 11 deaths.

The following causes showed a decreased mortality: whooping-cough, diarrheal diseases under five years, organic heart diseases, and diseases of the nervous system. Those causes showing an increased mortality were typhoid fever, cerebro-spinal meningitis, acute bronchitis, lobar pneumonia, broncho-pneumonia, pulmonary tuberculosis and Bright's disease of the kidneys. The mortality from the following causes remained the same: measles, scarlet fever, diphtheria and croup, diseases of the digestive organs other than diarrheal diseases, other tuberculous diseases and violence.

Viewed from the point of age grouping, the deaths of infants under one year of age showed an increased mortality of 21 deaths, between one and five years a decreased mortality of 24 deaths, between five and sixty-five years an increase of 98 deaths reported, and over sixty-five years of age a decrease of 33 deaths.

The death-rate for the first 24 weeks of 1914 was 15.05 per 1000 of the population, as against 15.25 for the corresponding period of 1913.

2. Davis in an interesting and well-presented article on calculous anuria, makes the following conclusions: The possibility of a reflex anuria cannot be absolutely denied, but convincing clinical, experimental and post-mortem evidence is still lacking. Analysis of these cases recorded in literature shows that at least in 90 per cent. either only one actively functionating organ existed, which was blocked, or that there was a blocking of both kidneys. The few cases reported as examples of reflex inhibition of an unobstructed but more or less diseased kidney, as the result of calculous obstruction of its fellow, are to be explained more rationally as the functional failure of an overloaded unsound organ. Convincing post-mortem and histological evidence of reflex inhibition of a sound kidney as the result of calculous obstruction of its fellow is lacking. Convincing clinical and experimental evidence is also lacking. From a practical point of view calculous anuria should be considered and treated as a purely mechanical problem. Operation should be resorted to at once in all urgent cases, the indication being to relieve obstruction, pyelotomy, when practicable, to be preferred to nephrotomy. Bilateral operation is indicated whenever the kidney first cut down upon seems inadequate by itself to sustain the work of elimination of the body.

3. Smith in a very careful and analytical paper finds that less than half of women having ectopic pregnancies have subsequent uterine children and about 14.6 per cent. repeat their ectopic pregnancies. The author removes the opposite even apparently healthy tube if further pregnancies seem unnecessary because of the danger of a repeated ectopic gestation.

4. The author believes that partial excision of the clavicle for sarcoma is a dangerous procedure, because of the great danger of metastases.

5. Albee's article, though not suitable for review, is of great practical value and well illustrated by plates and case histories. [E. H. R.]

9. Rapp reports on the effect of "enzytol" in the treatment of malignant disease. "Enzytol" is a boric acid salt of cholin, which is stable and non-toxic. It has been beneficial in various mouse tumors.

During the last year and a half, Rapp has made 25-30,000 intravenous injections of "enzytol" in malignant disease of different kinds. The dosage used has been from two to five or six c.c. of a 10% solution of "enzytol" diluted to twenty c.c. with physiological saline.

Rapp admits that his results are not striking and that they suffer from the fact that in the majority of the cases treated "enzytol" was combined with radium or other ray treatment. However, Rapp concludes that such a combined form of treatment in malignant disease produces subjective and objective results which are improving. Thus it is worth using until a better form of treatment is offered.

12. Huismans reports a case of sudden death which followed partial thyroidectomy for Basedow's disease. At autopsy a persistent thymus was discovered, and in the kidneys acute epithelial degeneration.

The similar cases which are reported have been attributed to a thyrogenic nephritis or to a condition of status-lymphaticus. Huismans believes that neither of these factors alone, accounted for his patient's death. It seemed more probable that the fatality occurred from a polyglandular intoxication which was exaggerated by the operation. Huismans considers that normally the secretions of the thymus and thyroid glands balance each other. Following the partial occlusion of the thyroid gland, an excess of thymus secretion entered the circulation, caused a severe intoxication and produced degenerative changes in the kidneys. Huismans suggests that in such cases, the complication may be avoided by the administration of thyroid tablets after operation. [R. F.]

BERLINER KLINISCHE WOCHENSCHRIFT.

No. 17. APRIL 27, 1914.

10. HERGENS. *Flexible Electrodes.*
11. DE PAGER, L. *On the Method of Boas for Detecting Blood in the Stools.*

2. Tietze reports two cases of children, each five years old, with tuberculosis of the lungs and also of the liver. In both the liver was much enlarged—in one case nodular, in the other smooth. There was also marked ascites. Talma's operation of omentopexy was done in each case, and the interesting fact was that there was no evidence of tuberculosis of the peritoneum or any other abdominal organ than the liver. Though the operation seemed to have no especially good result, both children were alive and in fairly good condition a year after they were first observed. In one of the two cases the diagnosis was confirmed by microscopic examination of a piece of the liver tissue.

7. As most favorable for radio-therapy the author mentions superficial growths on the face, cancer of the uterus, vagina and vulva, and also of the tonsil and parotid. Among those offering least hope are deep-seated growths of the face, and malignant tumors of the ovary and bones. Midway between the two groups he classes cancer of the breast, lungs, and gastro-intestinal tract. [R. H. M.]

No. 18. MAY 4, 1914.

8. KOCH, J. *Concerning Experimental Rhachitis.*
9. BRIEGER, L., AND SCHWALM. *Proving the Presence of Ferments and Anti-Ferments by Color-plates.* (*Löffler.*)

3. From the culture media of a series of selected strains of tubercle bacilli the author has been able to extract a substance which is a pure mucin, which he calls tuberculomucin, and which he has administered subcutaneously, both for prophylactic and therapeutic purposes, to a series of guinea-pigs and cows. In the guinea-pigs there was apparently no noticeable prophylactic effect, but in both animals there was a certain amount of beneficial action when the injections were given after the disease had been contracted. The number of observations have not so far been enough to warrant definite conclusions, and the effect on human beings has not yet been tried out.

5. This is a statistical review to show the infrequency with which the diagnosis of intercostal neuralgia is made. From 1400 neurological cases in a large hospital clinic Tobias could collect only five such cases, and of these three were clearly herpes zoster; from a large series of private cases only eleven came under this heading. He found it commoner in men than women, and more frequent on the left than on the right side.

6. Wechselmann reports a case diagnosed as either general paralysis or "syphilitic pseudoparalysis," apparently entirely cured by a series of twelve injections of salvarsan and intermittent treatments with mercury and potassium iodide. [R. H. M.]

2. SILVAN, C. *A Contribution to the Study of Neoplastic Metastases in Nervous Centers, with a Score of Observations.*
3. SISTO, P. *Studies on Progressive Pernicious Anemia.*

1. Tedeschi studied the effect of muscle fatigue on the vegetative nervous system, as indicated by its response to adrenalin, pituitrin, pilocarpin and atropin. The tests were made in normal individuals and in persons suffering from Graves' disease. In each case observations of the blood and the urine, heart tracings and blood-pressure readings were made. The writer finds that fatigue produces a greater irritability and sensibility to drugs in the nervous mechanism controlling circulation, both in health and disease. Further than this his results are inconclusive. [L. D. C.]

SURGICAL SECTION.

4. BARBERIO, M. *The Preparation and the Use of Antiformin.*
5. COLESCHI, L. *Radiodiagnosis of Bilocular Stomach.*

1. Antonelli studied the effects of oöphorectomy in young bitches who had hardly reached sexual maturity. He found that this operation produced the following alterations in the blood: A considerable diminution in the number of the red corpuscles and in the amount of hemoglobin, with slight increase of color index, a diminution of globular resistance, a certain amount of leucopenia with lymphacytosis and relative increase in the number of mononuclears. These changes in the blood persist for about two months. The writer concludes that the ovaries in health have, by virtue of their internal secretion, a direct stimulative effect upon the erythropoietic and sometimes also upon the leucopoietic organs.

3. Faginoli discusses the area of resonance over the extreme apex of the lung, to which Krönig first called attention in 1889. The determination by percussion of the width of this "isthmus" is of practical value in the early diagnosis of phthisis for narrowing of the isthmus is a very early indication of apical infiltration. Examination of the respiratory apparatus is not complete without the mapping out of this area. [L. D. C.]

SURGICAL SECTION.

1. LEOTTA, N. *Mechanic Ileus in Appendicitis.*
2. *CIGNOZZI, O. *Mcgalocccum and Appendicitis.*

5. *LEOTTA, N. *Pericecal and Pericolic Adhesions. (Conclusion.)*

2. Cignozzi makes clinical observations on two cases in which he did appendicectomy and cecoplication.

5. From his continued study of intestinal adhesions, Leotta concludes that in cases of soft adhesions, not extensive, and without constriction of the bowel, simple freeing of the adhesions is sufficient. In cases of extensive and solid adhesions, which have determined constriction or stenosis of the intestinal tract, a neostomy should be done, preferably a typhlo-transversocolostomy if the adhesions are associated with ptosis of the colon, otherwise a typhlosigmoidostomy. In very complicated cases, like some of Lane's forms, especially when associated with ileal reduplication and membranous pericolitis, resection of the intestinal tract may be indicated. [R. M. G.]

Obituary.

AMOS LAWRENCE MASON, M.D.

DR. AMOS LAWRENCE MASON, of Boston, died suddenly June 5, 1914, at Albany, N. Y., having been taken seriously ill with cardiac weakness while on his way from home to a fishing camp in Canada, which he annually frequented, for salmon fishing, of which he was very fond. Funeral services were conducted at Mt. Auburn by his cousin, Bishop William Lawrence.

Dr. Mason was born in Salem, Mass., April 20, 1842, and was the son of Rev. Charles Mason, rector of a church there. His mother was Susannah Lawrence, daughter of Amos Lawrence. He fitted for college at the Boston Latin School and at the private school of Epes S. Dixwell. He was graduated at Harvard in the class of 1863. Being the grandson of an eminent jurist, Hon. Jeremiah Mason, who was at one time United States senator from New Hampshire, Mr. Mason entered the Harvard Law School, but continued the study of law only half a year, then devoting himself to belles lettres for a year and a half, and to travel in France, Spain and Italy. He then returned home and entered the Harvard Medical School, from which he received the degree of M.D. in 1872. After studying a year or more in Germany he returned to Boston, where he practised his profession for many years, having also a summer practice, at one time in the White Mountains, and later at Bar Harbor, Maine.

He was visiting physician to the Channing Home for Incurables and for twenty years a manager of the Boston Dispensary. In 1877 he was appointed physician to out-patients, and in 1878 he became visiting physician to the Boston City Hospital, to which institution he gave a quarter century of active, zealous service.

Early in his professional career, from July 1, 1876, to Jan. 1, 1881, he was a member of the editorial staff of this JOURNAL, with his classmates, Drs. J. Collins Warren and George B. Shattuck, part of the time as assistant and part as associate editor.

Dr. Mason was president of the Suffolk District Medical Society in 1895 and for some time a councillor of The Massachusetts Medical Society. In 1898 he was president of the Boston Society for Medical Improvement. In 1891 he became a member of the Association of American Physicians, and in 1900 joined the emeritus membership of that society.

For twenty odd years he was a teacher in Harvard University, doing his work chiefly in the City Hospital wards, at first as instructor in auscultation, then as assistant professor, and finally as associate professor of clinical medicine, from which he retired in 1899. He continued his duties as visiting physician till 1903. He was then made senior physician till 1908, when he became consulting physician, virtually

an emeritus position, which he held at the time of his death. This gave a total continuous connection with the City Hospital of 36 years.

Dr. Mason was married to Louisa Steedman in 1874 and survived his wife by six years. He left one married daughter and two grandchildren. With this daughter he passed most of his winters in the South of late years, and his summers mostly at York Harbor, Maine. He was a member of the Massachusetts Society of Colonial Wars.

Besides writing a large number of medical papers, which appeared in various journals, he published in 1912 the "Memoirs and Correspondence of Charles Steedman (his father-in-law), Rear Admiral U. S. N., 1811-1890."

For twenty-five years Dr. Mason passed through his hospital wards daily during the period of his annual service. Few men have left there a stronger or more lasting impression. His good health and his conscientiousness contributed to make his daily hospital visit prompt, unfailing and unhurried. He made it a rule to give his personal attention daily to every patient.

In his relations with his colleagues of the medical and surgical staff he was ever ready to give and to receive counsel; and his hospitable manner of receiving views, not always identical with his own, was of a part with the courtesy which marked his every relation with his associates. In the deliberations of the staff his opinions were sane and sensible and were tersely but mightily expressed.

Several volumes of the Medical and Surgical Reports of the Boston City Hospital have his name among the editors, and he himself contributed numerous articles involving painstaking work. He also was ones of the editors of the history of the Hospital, which appeared in 1904, forty years after its foundation. Prior to the establishment of the "South Department" for contagious diseases, Dr. Mason took his turn of duty in the contagious wards of the main hospital, which were often much overcrowded. As a diagnostician, particularly in his favorite field of diseases of the chest, he was thorough and careful, and the autopsy room rarely refuted his accuracy. But he never would strain a point of diagnostic *finesse* at the expense of the strength or comfort of a very sick patient. His dealing with the patients as *persons*, even though they were of the social flotsam and jetsam, was always kindly and humane.

Dr. Mason accepted his responsibility for imparting his skill. For years he gave formal clinical instruction as professor of medicine in the Harvard Medical School. The hospital records still bear his pencilling in the margins, made before his clinics, and show the salient and pivotal facts which he wished to bring out in his discussion of the cases.

More intimate and more grateful than his formal instruction of the students in the amphitheatre and in the ward visits, was his fatherly manner of talk and of demonstration to the young men who served from year to year as his house officers. To their mistakes he was indulgent, of their oversights and negligences tolerant. Of him they learned lessons of patient study, of helpful therapy, medicinal and moral.

One of them, affectionately and piously, lays this wreath upon his tomb.

Miscellany.

AN IMPORTANT SANITARY PROBLEM.

During the last week in May there met at New York City a joint board of Canadian and United States sanitary engineers who were invited by the International Waterways Commission to advise standards of allowable pollution in the rivers connecting the chain of the Great Lakes. Some while ago Dr. A. J. McLaughlin, of the United States Public Health Service made an official survey of the entire Great Lake watershed, and at that time made the four following recommendations for remedies against the spread of disease in cities of that region by polluted water:—

"1. Safe water supplies, that is, water shown to be safe by daily bacteriologic examination.

"2. Supervision and control of water supplies by the state, to insure efficiency and a safe effluent (output of drinking-water) at all times.

"3. Control of sewage discharge within permissible limits, to prevent an unreasonable burden or responsibility upon filter plants.

"4. Prevention of pollution from vessels.

He recommended the formulating of two sets of standards for water:—

"1. Standards for filtered or treated water.

"2. Standards for raw (untreated or unfiltered) water at the intakes, which supplied the various lake shore cities."

Recently Prof. George C. Whipple, of Harvard, one of the three United States members of the board of advisors to the Waterways Commission, has discussed this subject at length, and his commentary seems to deserve republication in part as follows:—

"The particular task now before the commission is to decide what 'system of remedial or preventive works,' shall guarantee that 'waters flowing across the boundary shall not be polluted on either side to the injury of health or property on the other.'

"With the exception of the matter of controlling pollution by the discharge of sewage from vessels traversing the Lakes, the really international part of the commission's task is confined to the connecting rivers, namely, the St. Mary's River, connecting Lakes Superior and Huron; the St. Clair and the Detroit, between Huron and Erie; and the Niagara, between Lakes Erie and Ontario. The St. Lawrence,

through the Thousand Islands, may be added to the list. Along these rivers are a number of large cities and towns drawing drinking water supplies from these rivers, and getting from them a very bad and dangerous article indeed. Vessel pollution has made the water of the St. Mary's unfit for drinking use without treatment, even above the two cities of Sault Ste. Marie, on opposite sides of the boundary; while these two cities discharge their sewage into the river, and make its lower course, down to Lake Huron, and for some miles out into that lake, even fouler than its upper reaches. The American city of Sault Ste. Marie has had enormously high typhoid mortalities in recent years. In 1910 it had fallen to 23.7 per 100,000 inhabitants; but within the decade before that it had had mortality rates of 92.9, 115.9 and 172.9.

"Port Huron, at the mouth of the St. Clair, had in 1910 a typhoid mortality of 74.4. Detroit fares much better on account of having Lake St. Clair just above it on the waterway; but below Detroit the river of that name is grossly polluted by the sewage of the city, added to the constant defilement from vessels. Worst of all has been the city of Niagara Falls, where typhoid death-rates, due to drinking-water taken from the much polluted Niagara River, ranged for seven consecutive years above 126.6 per 100,000. This led to the recent installation of the two filter plants, as a result of which the typhoid fever rates have been much lower.

"One of the tasks now before the sanitary advisers to the Waterways Commission is to be the establishing of general standards of pollution of the boundary waters from which both Canadian and United States cities are practically compelled to draw their water supplies. As Dr. McLaughlin and I have already separately reported, the water supply problem for the lake cities which are not on or very near the connecting rivers is in almost every instance a local problem. The great bulk of the lake waters is notably pure and clean—free not only from disease-producing bacteria, but with a very scanty content even of harmless organisms. But the broad waters of the Lakes cannot be used for water supplies because it is not practicable to extend intake pipes or tunnels to points where the water is much more than seventy-five feet deep. This limits the length of intakes to distances which are often if not always within the range of polluting sewage from the very community the intake provides with drinking water. The longest intake on the Lakes is that of Cleveland, which is 26,000 feet long, and which extends about four miles from the shore. Each lake shore city therefore faces the necessity either of thoroughly purifying its sewage before it is poured into the lake,—which is impracticable for various weighty reasons— or of purifying either by filtration or disinfection the water supply it draws from the lake. The latter method is in the long run the cheapest and most efficient.

"Filters or disinfecting plants must not be overloaded, however; and here we have the main problem in connection with the waters of the boundary rivers. Water may be so grossly polluted that even disinfecting or filtration plants cannot purify them except at undue expense, and with too great a chance of disastrous breakdowns in the process. One obvious sanitary improvement is to check pollution of these rivers by sewage from vessels, which must be compelled to retain their sewage between river ports —and at ports, also, and made to discharge it where it will not endanger the water supplies of land communities.

"The problem as to the boundary rivers falls into several sub-problems. There is first to be considered how much pollution of these waters is compatible with thorough purification by adequate plants. Next, whether the existing plants, or such as the weakest of the communities affected can afford, can deal efficiently with this standard maximum pollution; and finally, what may need to be done in the way of more or less purification of the sewage from some of the cities to prevent their fouling the river waters beyond this allowable maximum of pollution.

"In the boundary rivers the problem is a health question of very serious importance. The solving of it can be carried by the commission only to the point of discovering all the facts, and making recommendations for improvement that are at once both adequate and within the financial capacity of the communities involved. After the standards have been set, and the recommendations made, there will be need of both official action on each side, and of a further campaign of education for the benefit of particular boards of health and health officers. While the situation of a considerable number of lake shore cities is bad, the gravity of the danger as a whole has in my judgment been much exaggerated. The problem is a local one for each community, and efficient purification plants have been built and successfully operated by a number of cities. Cleveland is to be commended for its recent action in deciding to filter its water supplies drawn through its long intakes, and to safeguard them still further by treating its sewage before discharging it into the lake. There is no valid reason why the water supply of every community cannot be made safe within an allowable limit of cost.

"The lesson of some of these plants, aside from the ability to ensure safe water supplies, is the need of competent superintendence, and on this head I would urge the recommendation of Dr. McLaughlin, that the operation and control of such plants be in the hands of competent graduates in sanitary engineering. His statement is worth repeating. He says:—

" 'The greatest obstacle to proper operation and control of plants has been the difficulty of securing the right man to place in charge of the plant. I have seen filter plants designed by our best engineers—perfect mechanism which if

properly handled would produce safe water—placed in the hands of an assassin who was a promoted stoker and absolutely ignorant of bacteriology or chemistry The best type of man for this position is a graduate in sanitary engineering. He will not only be conversant with the mechanical details of the plant, but will be able to adjust his chemicals according to the constituents and needs of the raw water. Most important of all, he will be able to make daily bacteriological examinations to determine the efficiency of purification. Nearly all the disasters due to sewage-polluted water supplies which have occurred were due to lack of daily bacteriological knowledge of the public supply or the inefficient operation of plants by unskilled men.'"

In view of the previous frequency and virulence of typhoid epidemics in cities drawing their water supply from the watersheds of the Great Lakes, the task of safeguarding and controlling these supplies becomes a sanitary problem of magnitude and importance.

YALE MEDICAL SCHOOL.

In the issue of the Journal for June 11 (p. 927) we commented editorially on the plans of the Yale Medical School for the celebration of its centennial, and for raising sufficient funds for its endowment. At the annual dinner of the Yale Medical Alumni Association, held in New Haven, Conn., on June 15, President Hadley announced gifts of $1,725,000 towards this sum.

"The family of the late Anthony E. Brady of Albany, N. Y., has advised the University of their determination to establish the 'Anthony N. Brady Memorial Foundation' of $500,000. It is provided that the income of $25,000 from this foundation shall be given annually for ten years to the university to enable the latter to declare operative at this time the agreement with the General Hospital Society and conclude an alliance between the New Haven Hospital and the Yale Medical School.

"If the university receives within this ten-year period a total of $2,000,000 for medical school endowment and building funds, exclusive of the gifts from the Brady family, the half million dollars will become the absolute property of the university. The Brady family has given $125,000 for the erection and equipment of a clinical and pathological laboratory.

"Toward the $2,000,000 sought for endowment the general education board has offered $500,000, provided $1,500,000 is secured by Jan. 1, 1916; unnamed donors have pledged $400,000 conditioned only upon the establishment of at least one memorial professorship in the medical school; Charles W. Harkness, '83, has pledged $100,000, and an unnamed alumnus adds another $100,000.

"President Hadley said only $900,000 remains to be raised for the endowment of $2,000,000 necessary to receive outright the $500,000 from the Brady family."

On Junt 19 it was announced that the anonymous gift of $400,000 is from members of the Lauder family of Pittsburgh, Pa., and Greenwich, Conn. The memorial professorship is to be the "Anna M. R. Lauder Chair of Public Health."

The formal exercises in celebration of the centennial of the Yale Medical School were held in Woolsey Hall.

"The introductory address was given by President Arthur T. Hadley, followed by the historical address by Dr. Walter Ralph Steiner of Hartford, who spoke on the subject, 'The Evolution of Medicine in Connecticut, with the Foundation of the Yale Medical School As Its Notable Achievement.' A formal address followed by Professor William Henry Howell of Johns Hopkins University on the subject, 'Premedical Studies in Their Relation to General and Professional Training.'"

The history of the Yale Medical School is interestingly sketched in a monograph published in conjunction with the celebration. A professorship in medicine was proposed at Yale in 1777, the Connecticut Medical Society was chartered in 1792; and the Medical Institution of Yale College was established in 1810 as the sixth medical school in the United States.

"In 1813 instruction in the Medical School was begun under Professor Nathan Smith, professor of the theory and practice of physic, surgery and obstetrics; Eneas Munson, professor of materia medica and botany; Eli Ives, adjunct professor of materia medica and botany; Benjamin Silliman, professor of chemistry and pharmacy, and Johnathan Knight, professor of anatomy.

"In 1814 the present South Sheffield Hall was purchased for the school, with the aid of a contribution of $20,000 from the state, and the first medical class was graduated."

WRECK OF A HOSPITAL SHIP.

Report from Glasgow, Scotland, states that the hospital ship *Maine*, presented to the British nation by American women during the South African war, was wrecked in the Firth of Lorne in a fog on June 17.

"The *Maine*, which was attached to the home fleet of the British navy, had a large number of patients on board at the time of the accident. All were placed in the ship's boats, where they remained until the arrival of other vessels summoned by wireless telegraphy.

"The *Maine*, as presented to the British navy in 1901, was the gift partly of President Bernard N. Baker of the Atlantic Transport Com-

pany and partly of the hospital ship *Maine* committee. The former presented the vessel, and the latter gave the elaborate fittings, which made the *Maine* one of the best-appointed floating hospitals ever constructed up to that time.

"The *Maine* was originally loaned by the Atlantic Transport Company, through its president, Mr. Baker, to a committee of American and Anglo-American women, of which Lady Randolph was chairman. The committee fitted up the vessel as a hospital ship, placed her in charge of American doctors and nurses, and sent her to Cape Town and Durban to care for the wounded and sick of the South African war. She received both British and Boer wounded, and afterward returned to Southampton with over 350 invalided British soldiers. She stayed there only nine days, being reëquipped with remarkable speed and sent back to South Africa to carry home another shipload of sick and wounded.

"It had been intended that the *Maine* should make a third voyage to South Africa, but when the crisis in China became acute it was decided that she could be used to better advantage in the Orient. She was therefore sent to Taku, and the *Maine* committee, through the United States representatives in Europe, informed the Powers of the departure of the vessel, and notified them that their wounded and sick would be cared for on her. Appreciative acknowledgments were made by all the Powers. The *Maine* returned from China in January, 1901.

"The ward capacity of the *Maine* was 210 beds. The surgeons and physicians, all of them first rank men from our best American hospitals, the nurses from the Mills training school, and the orderlies were all carefully selected. Despite the comparatively cramped quarters, modern scientific treatment had been carried out in the form of tub-baths for the cases of enteric fever, with gratifying results. By means of an admirable Roentgen ray apparatus, sent out from New York, valuable assistance had been obtained in the treatment of gunshot injuries, and in a well-equipped laboratory diagnoses of doubtful cases have been made by bacteriological examinations. A strange and happy fact to be recorded was that during the three weeks' voyage of this hospital ship home from South Africa the second time, not a single death occurred. After her return from China, as above noted, the ship was tendered as a gift to the British Government, and accepted in July, 1901. Since then she has seen constant service."

RECENT DEATHS.

DR. GEORGE PERLEY BRADLEY, who died of cardiac disease on June 11 at South Lancaster, Mass., was born in 1845. After studying medicine, he entered in 1869 the United States Navy medical corps, in which he served for 38 years, retiring in June, 1907, with the rank of medical inspector. He is survived by his widow.

DR. OTTO G. RAMSAY, who died on June 12 at New Haven, Conn., was born in 1869. He received the degree of M.D. in 1890 from the University of Virginia, and since 1899 had been professor of obstetrics and gynecology at the Yale Medical School.

DR. GEORGE DRESSER, a retired Fellow of The Massachusetts Medical Society, died at his home in Chicopee, Mass., on May 16, 1914, aged 76 years.

DR. SIMON MARX, a well-known gynecologist and obstetrician of New York, died on June 16, after a long illness, at the age of 49. He was graduated from the College of Physicians and Surgeons, New York, in 1884 and afterwards studied at Vienna, Berlin and Munich. He was formerly on the teaching staff of the New York Post-Graduate Medical School and Hospital, and at the time of his death was gynecologist to the Red Cross Hospital.

DR. FREDERICK F. R. BERLIN of New York died on June 14, at the age of 55. He was a native of Germany, and after coming to this country practised for some years as an architect. He then took up the study of medicine, and was graduated from the University and Bellevue Hospital Medical College in 1900.

DR. MAUS R. VEDDER, formerly a prominent practitioner in New York City, died on June 13 at his home in Caldwell, N. J., in his 80th year. He was a graduate of the College of Physicians and Surgeons, New York, in the year 1861. His son, Dr. Harmon R. A. Vedder, succeeded to his practice in New York.

DR. SIDNEY H. GARDINER of Brooklyn, N. Y., died on June 11, after an operation for appendicitis. He was born in Kingston, Ontario, on May 6, 1862, and was graduated from Queen's University, Canada, in 1889. He served for six years as adjunct surgeon to the Long Island College Hospital and was associate physician to Bushwick Hospital. He was a member of the Clinical Congress of Surgeons of North America and of the Kings County Medical Society. He is survived by his widow and by three daughters.

BOOKS AND PAMPHLETS RECEIVED.

The Value of Accurate Diagnosis in Disease by Beverley Robinson, M.D. Reprint.

Taschenbuch der Augenheilkunde von Dr. Curt Adam. Urban & Schwarzenberg. 1914.

Serology of Nervous and Mental Diseases by D. M. Kaplan, M.D. W. B. Saunders Co., 1914.

Practical Therapeutics by Daniel M. Hoyt, M.D. C. V. Mosby Co., 1914.

Black's Medical Dictionary by John D. Comrie. The Macmillan Company, 1914.

The Administrative Control of Smallpox by W. McWanklyn, B.A. Longmans, Green and Co., 1913.

Case Histories in Pediatrics, 2d ed., by John Lovett Morse, M.D. W. M. Leonard, 1913.

Artificial Parthenogenesis and Fertilization by Jacques Loeb. The University of Chicago Press, 1913.

Störungen der männlichen Geschlechtasfunktionen von Dr. Emil Kantorowicz, Arzt. Rebman & Co., 1913.

Technik der Ärtzlichen Massage von Dr. Anton Bum. Rebman & Co., 1913.

Leitfaden der Ersten Hilfe von Dr. J. Lamberg. Rebman & Co., 1913.

Taschenbuch der Magen- und Darmkrankheiten von Dr. Walter Wolff. Rebman & Co., 1913.

Taschenbuch der Diagnostik und Therapie der Lungentuberkulose von Dr. Heinrich Gerhartz. Rebman & Co., 1913.

Pathologisch-anatomisches Praktikum für Studierende und Ärzte von Prof. Dr. med. Richard Ostreich. Rebman & Co., 1913.

Text-Book of Anatomy and Physiology for Nurses by Amy E. Pope. G. P. Putnam's Sons, 1913.

Beriberi by Edward B. Vedder, A.M., M.D. William Wood & Co., 1913.
